Miller [12] reviews the opinions held by various authors for the causes of this condition and the pathological changes which occur. He reports briefly four cases he has met with where incontinence has followed labor. In three cases difficult operative work had been done, and one in which there were no appreciable lacerations present. He is convinced there is no single constant cause for this condition. It is found immediately after labor, when the urethra is bruised, edematous and swollen, and when the nerve supply is temporarily injured. Lacerations along the sides of the urethra and the sagging of the urethra give a more permanent cause. Several authors teach that the incontinence is due to a conically dilated posterior urethra, whereby the length of the urethra is diminished and the sphincter overstretched and weakened, and that this condition is brought about by a dilated and relaxed vagina and perineum and consequent sagging down of the pelvic organs.

In the treatment, the prophylaxis is most important. The proper conduct of labor is to allow the complete dilatation of the cervix and the emptying of the bladder before the application of forceps, and the timely use of forceps to prevent sloughing from prolonged pressure on the head, with careful and immediate repair of lacerations. The incontinence which immediately follows labor generally need give no alarm, for it soon disappears. Replacement of a retroposed uterus by a well-fitting pessary aids much the incontinence. The operative procedures for this condition are various and elaborate, depending upon the condition of the urethra and the bladder neck. In all cases the relaxed and torn introitus must be repaired, together with an appropriate operation for the retroversion if one occurs.

EXTRAPERITONEAL CÆSAREAN SECTION.

Doederlein,[13] of Chicago, writes a review of the history and technic of extraperitoneal Cæsarean section. Doederlein points out that the shortcomings and imperfections of the classical Cæsarean section has led the profession to search for other methods of delivery. Symphysiotomy and hebosteotomy (pubiotomy) appeared, and now the extraperitoneal Cæsarean section. Doederlein considers Ritgen, of Giessen, to be the first to have described this operation. This was in 1825. Others tried it with slightly different technic from that recommended by Ritgen, failed and gave it up. In 1870, or thereabouts, Thomas, of New York, wrote of it, and in 1876 Skene reported two successful cases. Up to 1880, Doederlein finds eight cases. The bladder was wounded in these. Maternal mortality was 50%, and child mortality, 42%. Doederlein remarks that the deaths attributable to the operation itself was almost *nil*. From 1880 to 1907 few if any cases were operated upon by this method. In 1907, Frank, of Cologne, revived the operation with slightly different technic. The advantages that Frank claims for this operation are that it avoids hemorrhage, that it avoids peritonitis, that it increases the range or indication. In other words, that it may be done when the classical Cæserean section is contra-indicated. Frank's technic is not extraperitoneal, for the peritoneal cavity is opened low down near the bladder. The vesico-uterine fold is cut and securely sutured to the peritoneum. The lower part of the uterus is then incised transversely and the fetus is allowed to be delivered spontaneously, if possible. In clean cases the

uterine wound is sowed up, but in infected ones left open and a gauze drain is placed and also one over the uterus through the vagina. By this method Frank reports having done thirteen cases, with no deaths. Fromme, in Veit's clinic at Halle, adopted this method with several modifications, and he feels that the good results obtained by it would warrant its use in many cases where now pubiotomy is regarded as the safer procedure. In 1908 Latzko, of Vienna, and Doederlein, of Munich, made still further changes in the technic, so that now it can be truly regarded as an extraperitoneal operation. Doederlein, of Chicago, gives in detail Prof. A. Doederlein's technic, which briefly, is as follows:

The bladder is partially filled. Incision is made, with the patient in exaggerated Trendelenburg position on the right side, from the symphysis to a point a little above the right anterior superior spine. The underlying structures are split and pushed aside. The right rectus is drawn to the left side. All bleeding points are carefully tied. The cervix and lower uterine segment is exposed by pushing aside the bladder and perineum, and a vertical incision is made in the most prominent part presenting in the external wound and carefully enlarged with scissors. Forceps are then applied to the head and the baby extracted. Placenta is removed manually or by Crédé's method. The uterus is packed with iodoform gauze, the end of which is passed out through the vagina. The uterine wound is sewed up with continuous catgut suture, the loose cellular tissue and bladder stitched over the uterine suture and the external suture is closed in the usual manner. If there is suspicion of infection, it is well to drain through the vagina. Professor Doederlein has, up to now, operated upon ten cases, all of which gave good results both to mother and child. Hemorrhage was very slight. The question as to drainage is still an open one. Some of the European operators are using it and some do not. Professor Doederlein holds that the extraperitoneal method is indicated in all cases where the Cæsarean section is indicated, and also in some cases where hebosteotomy or craniotomy would otherwise be resorted to. Two objections to this method are (1) inability to sterilize the patient, and (2) the possibility of rupture of the uterus in later pregnancies. The second objection is merely speculation, as the future alone can tell. Doederlein's article ends with a short bibliography.

PUBIOTOMY.

Williams [14] makes his second report on pubiotomy, covering now twenty-five cases. He writes fully upon the immediate results, the effects of the operation upon the patient, upon the pelvis and upon the labor. The indications and technic which he describes fully are those which he has developed from his own experience and from other operators. His conclusions are briefly as follows:

After pubiotomy the patients were delivered at once. There were no injuries to the bladder. There were six perineal and five deep vaginal tears. The relative infrequency of injury to the soft parts he attributes particularly to the extensive manual dilatation of the vagina and perineum prior to operating. The after treatment is not onerous. The patients suffer but little. Immobilization of the pelvis is not necessary, a four-inch adhesive strap around the trochanters being sufficient. The maternal mortality he feels should not exceed 2% provided the operation is performed by competent operators upon uninfected women. It is indicated in contracted pelves where the conjugata vera exceeds 7 cm. Prophylactic placing of the saw is indicated when it appears a problem whether the head can pass through the pelvis. In multiparæ with history of repeated difficult labors, or in primiparæ presenting extensive disproportions, pubiotomy is inferior, he regards, to Cæsarean section performed at the end of pregnancy. After the patient has been subjected to the test of labor, pubiotomy is many times less dangerous than classical Cæsarean section. Williams feels that pubiotomy should replace high forceps, prophylactic version, induction of premature labor and craniotomy on the living child. It should not be employed in infected cases or after failures to deliver by other means. In cases where the separation between the cut ends does not exceed 4 to 5 cm. the patients recover perfectly and are able to walk as well as ever. The bone section usually heals by fibrous union and a certain degree of permanent enlargement of the pelvis may follow, and occasionally in a subsequent pregnancy spontaneous labor may occur.

Reports of Societies.

NEW ENGLAND PEDIATRIC SOCIETY.

The New England Pediatric Society held its eleventh meeting on Saturday, May 21, 1910 at 8.15 P.M. in the Boston Medical Library.

The following papers were read:

William R. P. Emerson, M.D., Boston:

THE CLASS METHOD IN THE DIETETIC AND HYGIENIC TREATMENT OF DELICATE CHILDREN.[1]

Arthur I. Kendall, M.D., Boston:

LACTIC ACID BACILLI. WHAT THEY ARE AND WHAT THEY ARE SUPPOSED TO DO.[2]

Robert M. Merrick, M.D., Boston:

THERAPEUTIC USE OF SEA WATER IN INFANTS.

DISCUSSION, DR. EMERSON'S PAPER.

Dr. J. L. Morse: I think Dr. Emerson is to be congratulated for showing us a practical method of applying the attention to details which we all, I suppose, give to our private patients, to a larger number of patients in dispensary practice. So far as I know, his record to-night is unique. It certainly points out an entirely new field. I was a good deal interested in what he said about the children not doing as well when they went away to the country in the summer. That, I believe, has been the experience of the French when they have sent children away from Paris to the country in the summer. These children almost always came back in poorer condition than when they went away. This was attributed to the facts that they were not so carefully supervised, that their food was often not as good as they had been getting at home, and that they often had to work harder than they did at home.

Dr. Emerson: The first year I was simply feeling my way along. I believed if a child did not gain, the reason could be found, but I was not absolutely sure that such would be the case. The second year, however, has demonstrated to my satisfaction that either the hygienic or the organic cause can always be found. If the child does not gain after the hygienic conditions have been thoroughly studied, we are led to look again for an organic cause. In one case I began all over again with the physical examination, until I got to the throat. The more careful examination showed diseased tonsils and adenoids, lying too deep to be seen in the routine examination. The diseased tissue was removed the following day and the child immediately began to gain. In this way in several cases the class has helped in diagnosis by exclusion. From the first the class has been practically self-supporting. We charge five cents for the record books, and the mothers make the tents themselves. It seemed advisable to get the children away for the summer. One of the poor mothers said she would take three of the children with her own three. Those who graduate from the class, by gaining normal weight and health, are given a small diploma, which is the only special inducement offered the children for coming to the class.

Dr. F. T. Murphy: There is one point concerning the class system which I would like to speak about, and that is the one to which Dr. Merrick has already referred. I think Dr. Emerson has in a small way indicated work which might be done in a very large way with gratifying results. Hygienic measures now employed in the public schools fall short of the mark. I think the very fact that we show gain in weight in many of the children who are attending the tuberculosis class at Franklin Park is an indication that we should also adopt dietetic measures; that is, that the mothers should be taught in classes how to care for and how to feed their children. I think we are harping too much on the open-air part of the public school system and too little on dietetic measures, which should be used in every instance in order to get the best results. The children then, instead of being what we call pretubercular, anemic and underfed, would be a great deal stronger. At the tuberculosis school at Franklin Park each child has an active tubercular lesion in the lungs, or gives a positive Von Pirquet reaction. In many cases we get positive sputum. All are benefited by the open-air treatment, but it is the proper feeding of the children which is doing so much in helping them along. I think that the class method which Dr. Emerson has used as applied to the mothers of the children is an excellent thing. If we could have open-air rooms in the public schools, on the road or some other place, joined with a class system of teaching mothers how to prepare food and properly feed their children, we would make a long stride in the right direction.

Dr. Hastings: I would like to ask Dr. Emerson if he had any difficulty in getting the children to take the milk. In private practice children often say they do not like milk and will not take it. Dr. Emerson said in his paper that only those who did take the milk made the gain, and I would like to ask if among the children of the poorer classes he has experienced any difficulty in getting them to take it.

DISCUSSION, DR. KENDALL'S PAPER.

Dr. J. L. Morse: There are a number of points in Dr. Kendall's paper which, it seems to me, deserve special emphasis. One of them is the influence which the food has in modifying the intestinal bacterial flora. We are all very likely to forget not only this fact, I think, but also that it in many, if not most, instances renders the administration of bacterial cultures unnecessary. Another very important point is that the Bulgarian bacillus and other organisms of the same type act only in the small intestine and can be expected to do good only when the difficulty is located there. A most important point is that these lactic acid bacilli may do harm as well as good. Consequently, if we use them in a routine way, giving them freely in nearly every case, as so many do, we are perhaps just as likely to do harm as good. Judging from my own experience, it is impossible to determine from the clinical signs and symptoms in what case they are likely to do good and in what case they may do harm. Another point which has been called to my attention pretty strongly recently by cases that have come to me after treatment by other physicians is that a good many physicians are attaching too much importance to the presence of indican in the urine. Some of them are making diagnoses of serious intestinal lesions, and giving most unfavorable prognoses simply on this basis, drawing conclusions which, it seems to me, are entirely unwarranted.

Dr. F. B. Talbot: This subject is particularly interesting to me as I have been studying the effect of the various food components on the digestion of infants from the chemical point of view, and I believe that bacteriology explains certain things that we observe in the feeding of sick babies whose powers of digestion are lowered which chemistry does not explain. It is perfectly conceivable that an overgrowth of certain bacteria which were otherwise normal inhabitants of the intestinal canal may have a harmful influence on digestion. The whole subject is so complicated that it is impossible as yet to draw broad conclusions.

THERAPEUTIC USE OF SEA WATER IN INFANTS.

Robert M. Merrick, M.D., Boston: The use was suggested by the experience of Simon in his Boston

[1] See Journal, p. 326. [2] See Journal, p. 322.

lecture. The water was obtained off the "Grand Banks" and prepared according to the Simon technic. It was used in 12 cases of bronchopneumonia, 16 cases of congenital debility and 19 cases of acute and chronic intestinal indigestion. The result, on the whole, was poor in each class of cases and led to the conclusion that the subcutaneous injection produced no remarkable results, and in the experience of the writer equally good results were obtained in some cases treated by saline solution. Emphasis was laid on the usefulness of saline isotonic solutions in general circulatory weakness, especially as seen in infectious fevers.

DISCUSSION, DR. MERRICK'S PAPER.

DR. R. W. HASTINGS: Quite a number of these cases came under my care because I came on duty the first of January, Dr. Merrick's service ceasing in December. I am a little annoyed to see that the children who did well in the pneumonia cases were mostly before I came on duty. Certainly after I came on duty and carried out the treatment as Dr. Merrick had started it, I was not impressed with the effect that the sea water had on them. I started a parallel set of cases who would be having a salt solution, but after discussing the matter we found the amount of material was too small for that, and we thought it would be better to try and get fifty cases and see what would be the result with this treatment. One interesting thing, perhaps you caught it as Dr. Merrick read his paper, was the case of edema which seemed an effect from the subcutaneous use of sea water at first, but was relieved by doubling the dose. This was done at Dr. Leary's suggestion. I do not know any explanation of this and did not understand it at all at the time.

The class of cases at St. Mary's Infant Asylum which interests me most and baffles me most completely is these inanition cases, and after reading Dr. Simon's description of the wonderful results which would certainly come from the administration of sea water, and having tried all the different methods on successive sets of children, and finding them steadily going to the bad, no matter what we did, I was quite enthusiastic to try the sea-water treatment. This is the second set that Dr. Merrick reported, and you will see that they all did badly just the same whether they had sea water or not. After such a lecture as was given by Dr. Simon, in which he made such extraordinary claims both for the infectious diseases and for the inanition cases, it seems to me that such an investigation as Dr. Merrick has carried on ought to have a good deal of weight with us and help to eliminate undue authority which might otherwise be accepted from the words of a man who speaks with so great positiveness. Personally, I want to try the salt solution and give it in a similar series of cases and see whether we will not have just as good results, perhaps better, from the use of the normal saline solution as we do from the use of the fluid which the Frenchman thinks is "that out of which all animal life came."

Book Reviews.

Hygiene and Morality. A Manual for Nurses and Others, Giving an Outline of the Medical, Social and Legal Aspects of the Venereal Diseases. By LAVINIA L. DOCK, R.N. New York and London: G. P. Putnam's Sons. 1910.

It is a pity that this volume, which should have been a useful document in the campaign against venereal disease, should have been made a polemic in favor of woman suffrage. Whatever individual opinion in this matter may be, an avowedly impartial scientific work is not the place for its exploitation. Doubtless publicity and education are the chief agents by which we may hope ultimately to stop prostitution and its consequences, but their action and value are only hampered by partisan argument. Doubtless, too, the influence of good women must be the greatest inspiration in this conflict, as it is in all human progress and achievement, but that influence loses much of its force when those who seek to exert it assume the attitude that man alone is responsible for existing evils, and, therefore, "chuck him out, the brute." It is probably true that "you can lighten the curse of Adam when you've lightened the curse of Eve." The converse is probably also true, and mutual charity is the best means towards mutual betterment, whether in hygiene, morality or other social conditions.

The Surgery and Pathology of the Thyroid and Parathyroid Glands. By ALBERT J. OCHSNER, A.M., M.D., U.D., and RALPH L. THOMPSON, A.M., M.D. St. Louis: C. V. Mosby Company. 1910.

This work, dedicated to Dr. Charles H. Mayo, represents the results of the senior author's personal surgical experience in the treatment of thyroid disease, and of the junior author's studies of thyroid pathology and of the anatomy, physiology and pathology of the parathyroid glandules. The book, which is essentially a manual of regional surgery, is most admirably illustrated by many text figures, and by a series of forty full-page plates presenting detailed steps of operative procedure. There is also an abundant special bibliography of parathyroid literature. The work seems a valuable contribution to the technical knowledge of this important branch of surgery.

Clinical Examination of the Urine and Urinary Diagnosis. A Clinical Guide for the Use of Practitioners and Students of Medicine and Surgery. By J. BERGEN OGDEN, M.D. Illustrated. Third edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1909.

This third edition of a standard textbook represents a careful revision of the original material, with omission of some matters not of clinical importance, description of many improved methods and changes in technic, and addition of a new appendix on examination of the urine for the purpose of life insurance. It is unfortunate that there is but a brief consideration of the urine in pregnancy, and that the author dismisses puerperal eclampsia with little more than the statement that it "in all probability is identical with uremia," and without any account of methods of determining the ammonia coefficient. Apart from this, there is nothing to criticise and everything to praise in this work, which should continue with increased efficiency its valuable service to the profession.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 25, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

FLORENCE NIGHTINGALE.

IT is a curious reflection that a brutal, ineffectual and now almost forgotton war should have been the agent which made manifest to the world the genius of Florence Nightingale. Without that war, or in spite of it, her mission would have been ultimately accomplished, but more slowly, less effectually and less strikingly. Her methods were fundamentally correct, therefore her results must have been inevitable, but the Crimea pushed them to a sudden fruition.

Miss Nightingale was one of the most remarkable of her sex, one of the greatest women who have lived. Her life should be a classic for every young girl to read, to study, to ponder and, in so far as may be, to imitate. Now that she is dead, it is to be hoped that her family will authorize a biography which will necessarily be more accurate and complete than any book at present available.

It is certain that she possessed in the highest degree all the attributes of perfect womanhood. She was always, in thought and act, a lady. Her single obvious limitation was a delicate body, progressing to almost complete invalidism, yet so admirable was her regard for the rules of health she taught so well that she lived ninety years of most intense physical and mental effort. She possessed in a truly wonderful degree the genius of organization, together with those other qualities, most rare in man and in woman, an enormous comprehension of detail, combined with unerring deductive reasoning, from multitudes of isolated facts; these two attributes represent opposite poles of mental action and characterize only the greatest minds. Hers was the unusual fortune of completing the work she undertook and receiving the reward of her fellow-beings while she lived.

Florence Nightingale was to an unusual degree responsible by her individual efforts for her success. She achieved greatness. She inherited from parents definite intellectual gifts, but she outstripped them far in the development of these traits. She struggled against caste and tradition far more powerful than anything we know to-day, and while the breadth of character transmitted by her father helped her in the fight, it certainly robbed the struggle of but little of its intensity. Her mother was a charitable lady of the highest type, a woman of decision and mental power, yet this did not make the horrors of Scutari the less real or the more easy to overcome. Miss Nightingale's greatest glory must rest in the fact that, recognizing correctly her own natural powers, she also estimated and realized the colossal nature of the task before her. From the beginning she knew that it could be conquered only by the most complete and thorough preparation, backed by unflinching determination, singleness of purpose, calm judgment, physical courage and ever-ready sympathy. She illustrates well the fact that the really great possess natures so rounded and complete that they instinctively understand all manner of men, and in return all classes find in them a responsive chord. So it happened that Miss Nightingale was worshiped by the soldiers, respected and consulted by the officers, adored by the country people, accepted as an equal by the nobility, recognized as an authority by the scholar, and honored by royalty.

It is impossible for us to-day to picture accurately the world without trained nurses and trained nursing; we accept them as matter of course, as we accept the telephone, the automobile and to-morrow the aeroplane. Yet the difference that exists between proper nursing and the lack of it, between present conditions throughout the earth and those of sixty years ago, is stupendous and almost incomprehensible. It is a change which has fortunately improved the lot of the poor more than that of the rich. Medical men have been given a wonderful privilege in the fight for humanity against pain and disease, yet it may be seriously questioned whether, in the last half century, the trained nurse has not saved as many lives and alleviated as much suffering as has the physician. And this great opportunity has been made possible for all women by the efforts of one woman, who may well be considered for generations to come the model, the ideal and the glory of her sex.

THE GROWTH OF A GREAT LONDON HOSPITAL.

The London Hospital has recently been brought into special notice through a visit from the king. In connection with this event, the *Daily Mail* has gathered certain statistics which are of interest not only in relation to this hospital, but as an evidence of the extraordinary development of hospitals in general during the past two centuries.

The first year's work of the London Hospital was undertaken in 1740, in the reign of George II, and one hundred and twenty-seven patients were treated, with a very large percentage of recoveries, according to the records. As contrasted with these modest figures, it is stated that the present yearly work of this hospital is fifteen thousand in-patients and one hundred and eighty-two thousand out-patients, with the employment of seven hundred nurses, fifty resident doctors and instruction to five hundred medical students. It is hard to realize that less than two hundred years ago practically nothing was known of hospital hygiene, nurses in any modern sense had not yet come into existence, and treatment was crudely empirical. One sympathizes with the prejudice, not yet wholly extinct among certain classes of the community, against hospitals in general, when one reads of the really barbarous methods employed even in this great institution in the early days of its history.

In 1830 a physician wrote, "We always engage nurses without a character, as no respectable person would undertake so disagreeable an office." Any selection of diets to meet individual needs was wholly unknown, and the simplest rules of sanitation were ignored.

What the future may bring forth in the treatment of the sick may only be conjectured, but the possibilities of relief of human suffering take on an added significance in the light of the progress during the past fifty years. We speak at length in another column of the great work of reform instituted by Florence Nightingale, perhaps the most significant individual medical accomplishment of the last century, but hardly less remarkable has been the general awakening both within and without the profession to the opportunities of the present and the possibilities of the future. Of this the London Hospital stands as one of many examples.

MEDICAL NOTES.

Investigation of Pellagra. — The Surgeon-General of the United States Army has detailed Capt. Joseph F. Siler and Capt. Henry J. Nicholls, of the Medical Corps, to assist the commission appointed by the governor of Illinois in the study of pellagra in that state.

Cholera has Invaded Italy. — The disease has appeared in several towns on the Adriatic Coast, among which the town of Trani is most severely affected. Up to Aug. 18, 44 deaths had been recorded. The epidemic appears to be unusually virulent, with a mortality of over 75%, and often with fatal results within a few hours after outset. Dr. Ruetti, of Rome, who has been appointed royal commissioner with full powers, aided by the Red Cross Society, is directing the fight against it. The king himself is reported as about to visit the district unless the course of the invasion is stayed. Later reports are somewhat more reassuring.

The Mechanical Age in Germany. — News comes from Berlin giving two new uses for "horseless vehicles." In the army, field surgeons are to be mounted upon motor tricycles, built to stand rough work and equipped with a large box or basket for carrying first-aid appliances.

It is intended by this means to secure speedy relief for the wounded, thus doing away with one of the horrors of the battlefield. The tricycle is furthermore so arranged that it may serve as an ambulance, to carry those most in need to the field hospitals.

Another innovation is the equipment of a corps of hospital nurses in Berlin with bicycles. These nurses, equipped with small outfits which they strap to their bicycles, start immediately to the scene of any accident and frequently render first aid before the ambulance arrives.

Golf at the Meeting of the British Medical Association. — From the point of view of golfers the annual meeting of the British Medical Association, according to the *British Medical Journal*, must have been at least as successful and enjoyable as from that of those not affected with this mania. Thanks to the energies of Dr. F. J. Smith and those who co-operated with him in attending to their interests, golfers had the opportunity of testing the virtues of practically every first-class course within easy reach of London. In addition there was the usual annual match between teams drawn from golfers resident in the locality in which the meeting is being held and visitors. The match took place this year on Wednesday afternoon at Northwood Links, the arrangements made by Mr. Percy Furnivall

working out to general satisfaction. It proved what is known as a very close thing, London winning at length by ten matches to eight.

A Possible Aid in the Diagnosis of Malignant Disease.— In a recent number of the *Lancet* is published an article by Dr. Elsie M. Royle on the aid which chemical examination of the urine may afford in the diagnosis of malignant disease. Dr. Royle's investigations have enabled her to prove that in cases of cancer the uric acid is usually higher than is found in healthy cases under similar conditions; further, that the output of phosphates in the urine is, in the majority of cases of cancer, decreased when compared with healthy individuals; and, finally, that the ratio of $\frac{\text{phosphates}}{\text{uric acid}}$ is almost invariably reduced in malignant disease. Acting on these results, Dr. Royle suggests that a chemical analysis of the urine may prove of value as an aid to diagnosis in obscure cases of cancer, especially when the abdominal organs are the seat of the disease. The differential diagnosis of malignant disease from gallstones, gastric ulcer, chronic pancreatitis and other morbid conditions is frequently very difficult, and any reliable auxiliary test would be welcome. Dr. Royle, however, prudently observes that her investigations are not complete and that this communication is only intended as a preliminary one. The cases she has examined point to the proposed test as a useful one, but before the value in diagnosis of the facts proved in her paper can be clearly established, it will be necessary to determine how far they are true of other forms of cachexia, and what their relation may be to the secondary anemia usually present in malignant disease. Dr. Royle is at present engaged in working out these questions, and the results will be awaited with interest. The technic of the chemical tests is not a complicated one.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Aug. 23, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 34, scarlatina 20, typhoid fever 35, measles 18, smallpox 0, tuberculosis 72.

The death-rate of the reported deaths for the week ending Aug. 23, 1910, was 18.87.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Aug. 20, 1910, was 232, against 223 the corresponding week of last year, showing an increase of 9 deaths and making the death-rate for the week 19.21. Of this number 130 were males and 102 were females; 126 were white and 6 colored; 148 were born in the United States, 80 in foreign countries and 4 unknown; 43 were of American parentage, 154 of foreign parentage and 35 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 36 cases and 1 death; scarlatina, 16 cases and 0 deaths; typhoid fever, 21 cases and 3 deaths; measles, 19 cases and 2 deaths; tuberculosis, 71 cases and 17 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 18, whooping cough 1, heart disease 21, bronchitis 1. There were 19 deaths from violent causes. The number of children who died under one year was 59; the number under five years, 78. The number of persons who died over sixty years of age was 53. The deaths in public institutions were 103.

Cerebrospinal meningitis, 1 case. Anterior poliomyelitis, 2 cases and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 5 cases and 4 deaths. Measles, 3 cases. Typhoid fever, 1 case. Diphtheria, 2 cases.

Deducting deaths of non-residents, the total is 203 and the death-rate is then 16.81.

Poliomyelitis in Rhode Island.—A considerable number of cases of poliomyelitis have appeared in Providence, R. I., and vicinity. On Aug. 16, six new cases were reported.

Typhoid Fever in Worcester and Vicinity. — The direct relation between typhoid fever and infected milk is illustrated by the epidemic in Worcester. By Aug. 15 the Board of Health reported fifty-three cases among the customers of one milk dealer.

This dealer, it is stated, is allowed, notwithstanding, to continue his delivery as before the epidemic with the exception that he must not handle milk from one specified dairy. It is to be assumed that the Board of Health has traced the infection to this source. Even if this were true, it is to be hoped that the milk man thoroughly boiled his cans, his milk-house and his wagons on the day he ceased handling the polluted supply.

Cochituate, a village twenty-five miles from Worcester, has had more than eighty cases of typhoid, with three deaths, within the past three months. The infection there is also believed to be due to contaminated milk.

NEW YORK.

A CENTENARIAN. — Mrs. Margaret Johnson, a negress, the oldest woman on Long Island, and probably in the state of New York, died at her home at Bayside, N. Y., on Aug. 17, at the alleged age of one hundred and ten years. She is stated to have been born in New York City on May 15, 1800. She was the mother of ten children, but is survived by only one daughter.

8. SAUER, J. G. *Aerotherapy.*

2. Fox reports five cases of tetanus and discusses the prophylaxis and treatment of this disease. The prophylactic treatment of wounds is of far greater importance than the treatment of tetanus after it has developed. The serum should be used prophylactically in all cases of punctured or deep wounds, where the anaerobic tetanus bacilli can grow. This is especially important in localities where tetanus is of frequent occurrence, as in New Jersey and Long Island. Tetanus bacilli are not uncommon in the human feces, especially if the host works around horses; for this reason thorough purging and restraint from uncooked food has been recommended for three days prior to operations in regions exposed to fecal contamination. In treatment, the serum is probably best given by the intraspinal or intraneural method. From an analysis of twenty-four cases collected from the literature, the writer finds that the intraspinal injection of magnesium sulphate is probably of great value and deserves a wide clinical trial. 8. Dorrance and Ginsburg advocate vein-to-vein transfusion of blood instead of artery to vein. They claim as advantages: (1) Its simplicity. (2) Lack of risk both to donor and donee in the matter of too rapid loss of blood for the donor and the danger of acute dilatation of the right heart for the donee. (3) Superficial vessels instead of deep ones are used and are easy of access and control. They believe these things offset the quicker but more difficult artery-to-vein method, even though, with the latter, the donee is getting purer, more oxygenated blood from the artery of the donor. Their method has been tried on one human case with success. [E. H. R.]

7. BROWN, L., AND SMITH, D. *The Cultivation of Tubercle Bacilli Directly from Sputum by the Use of Antiformin.*

1. Zinsser, using washed leucocytes from rabbits, performed a series of experiments, from which he concludes as follows: "Extracts of normal rabbit leucocytes, both those obtained by aqueous extraction and those obtained by freezing in salt solution, have distinct bactericidal powers for pyogenic staphylococci and for Bacillus typhosus." By testing the thermostability of these endocellular bactericidal substances, he showed that they are distinct from the bactericidal substances in serum. Quantitatively, they are much less than the latter; they are probably sufficient only for destruction of bacteria ingested by the leucocytes. They were not increased by immunization.

2. Sappington reports a series of twenty-two typhoid cases treated with typhoid vaccine. He also inoculated three non-typhoidal patients by way of contrast. In the latter, there was marked local reaction, but no general reaction save increase in opsonic index and agglutinins. The typhoid cases, on the contrary, showed almost no local reaction. In about 75% of these twenty-two cases, "there was distinct improvement sufficient in degree and rapidity of development to be foreign to the usual course of typhoid fever."

The treatment must be begun early, and a small dose of five million bacilli is to be tried first. This is to be rapidly increased, but the amount and frequency of dosage must be regulated by the reaction and the opsonic index.

4. Anderson and Goldberger conclude from their experiments that Rocky Mountain spotted fever and tabardillo are distinct diseases. The blood of infected persons is infective on at least the eighth day; inoculation of monkeys with such blood is positive, and one attack of the disease confers immunity. The blood serum when filtered is no longer infectious. The writers believe the body louse to be the carrier of this disease. [G. G. S.]

13. TAUSSIG, F. J. *Syphilitic Fever in Pregnancy and the Puerperium.*

2. Williams, Cragin and Newell conclude from a review of the literature on vaccine therapy in gynecology and obstetrics that opsonins undoubtedly play a part in the production of active immunity. The determination of the opsonic index is difficult technically and uncertain in value. In chronic gonorrheal arthritis and urethritis opsonic treatment is a valuable adjunct to other treatment and may alone lead to cure. It appears to be useless in acute infections. It is more efficient in the treatment of vulvovaginitis in children than any other means, but even here it does not always cure. In infections of the urinary tract due to the colon bacillus it sometimes results in a symptomatic cure, but rarely relieves the bacteriuria. In the pyelitis and pyelonephritis of pregnancy there is no evidence that it does more good than the usual rest and urotropin treatment. In certain cases of endometritis it appears to reinforce the curative influence of the curettage.

6, 7, 8. In the symposium of three articles on the surgical treatment of puerperal septic infection (1) Vineberg advocates the ligation of the pelvic vein in pelvic thrombophlebitis, but his and quoted cases show a high mortality. (2) Montgomery has used the antistreptococcus serum to advantage. He warns that a patient convalescing from sepsis should never be considered out of danger as long as the pulse remains persistently rapid, even though the temperature does not rise above normal. This rapidity of pulse is almost always an indication of a slumbering process which may at any moment become active. (3) Polak states that the number of puerperal infections is increasing, but that the mortality is lower owing to our increased knowledge of treatment. He warns us to be more conservative, for he believes that any intrapelvic or intra-uterine manipulation made during the acute stage of a puerperal sepsis always breaks down and disturbs nature's protective barrier and permits the dissemination of the infection through freshly abraded or penetrated surfaces. Never disturb a local focus post-partum as long as the patient shows improvement, unless there is a definite localization of pus. Nature is competent in the majority of instances to localize and circumscribe the infection. Operations should be avoided if possible. Thrombophlebitis is a conservative process on the part of nature to limit the spread of infection, and any form of pelvic manipulation only tends to break down and separate parts of these thrombi and extend the infection to more remote parts.

10. Blake believes that in recommending an abdominal operation to relieve neurasthenia the following four conditions must be satisfied:

(1) That there is a definite morbid or mechanical perversion of the normal condition of the viscera.

(2) That it is the chief underlying cause of the neurasthenic state.

(3) That the neurasthenic condition cannot be cured without its correction.

(4) That it can be corrected by a definite operative procedure of only moderate danger to life.

11. MAGRUDER, E. P. *Bonegrafting and Osteoplasty. A Case of the Latter Presented.*
12. *CROSSEN, H. S. *A Deceptive Form of Appendicitis in Women.*

2. Harris, reviewing the condition of 77 women claiming injury to the pelvic organs after trolley-car and other like accidents, comes to the following conclusions: (1) Miscarriages during the first four months of pregnancy readily occur, often from comparatively slight injuries, or even fright, but after the fifth month they very rarely occur from such causes. (2) Car accidents and the like seldom if ever cause disease or displacement of the pelvic organs in women whose organs are normal and healthy at the time of the accident. (3) Women with chronic pus tubes or other pelvic inflammations may have acute exacerbations of their troubles excited by accidents producing general injuries. (4) Women with old lacerations, displacements, prolapses, etc., may have the symptoms resulting from such conditions temporarily aggravated by general injuries and are often particularly prone either consciously or unconsciously to attribute all of their troubles to such injuries, which had little or nothing to do with causing the conditions present. (5) Accidents producing general concussion of the body may produce a temporary irregularity in the menses, usually increasing them, but occasionally suspending them, which functional derangements seldom last longer than three or four months.

8. Wilson and his associates, experimenting with the Cammidge test, conclude finally that as a means of diagnosing disease of the pancreas it is both valueless and mis-

leading, and that there is no apparent clinical relationship between disease of the pancreas and any of our various types of end reaction. It does not seem that the end reactions are artifacts, but rather that they indicate actual metabolic variations. The relation of these changes in metabolism to the welfare of the patient is not apparent.

12. Crossen describes two very interesting cases of retrocecal appendicitis in which the appendices were so buried in the wall of the cecum that they were indistinguishable from the outside, but formed masses inside the cecum which were mistaken for adnexal disease before operation. [E. H. R.]

2. Reicher compares the malignant tumors of animals with those of man and thinks that they have enough points in common to consider them in the same class. He then reviews the different methods that have been tried to check the growth of tumors in animals by the injection of different substances. He uses injections of adrenalin solution in the tissues around the tumors in mice and rats and has succeeded in causing necrosis of adenocarcinoma and sarcoma. By using the adrenalin injections before inoculating the rats with tumor he has diminished the frequency of successful inoculation. [C. F., JR.]

16. ADAM, C. *Gonorrheal Ulceration of the Cornea.*

1. In a series of 568 cases of hemorrhage of the uterus, 505 were treated by operation and 63 by the x-ray. The writers believe that radiotherapy rightly used will give success in a great many cases where operation would be dangerous, and that in this way mortality can be lowered. They consider operation to be the treatment of choice, however, for strong people and especially for the poor, who must be able promptly to return to their duties. Of the cases that received radiotherapy, amenorrhea was brought about in 60%, oligomenorrhea in 30% more (i. e., sufficient result), but two cases became discouraged and desired operation.

2. The experiments of Fischer and Hoppe are interesting and important from the point of view of serology and scientific therapeutics. [G. C. S.]

BERLINER KLINISCHE WOCHENSCHRIFT. No. 29.

JULY 18, 1910.

2. LONDE, P. *Pericholecystitis.*
3. LASSABLIÈRE, P. *The Influence of Toxins upon Nitrogen Metabolism.*
4. *THERRE, A. *Experimental Study on the Action of Vichy Water upon Arterial Tension.*

4. Therre has studied the effects upon arterial tension in goats of the various Vichy waters. The experiments are so conducted that the animals are subjected to the least possible change. Considerable variation is found in the different waters, even if their temperature and mineral content are the same. With only one exception he noted a marked rise in tension, which was maintained for a prolonged period of time. The "maximum and minimum" pressure went hand in hand. But the variation was not always in direct proportion to the amount of fluid administered, either by mouth or subcutaneously.

[L. H. S.]

Correspondence.

CANTERBURY.

[From Our Foreign Correspondent.]

Dover, July 31, 1910.

Mr. Editor: We did not, like Chaucer, lie "in Southwark at the Taberd," but when we finally did turn our backs on London we were

> "Ready to wenden on our pilgrimage
> To Canterbury with ful devout corage."

Unlike his good pilgrims, however, we broke our journey only at Rochester, a pleasant town with a fine old Norman castle and a cathedral that shows many traces of the ruthless hand of ignorance. A nearly effaced tablet near the West Gate still preserves, notwithstanding, the pious memory of one godly "decani Roffensis" and with it of the Roff's camp of the Romans, which, through the Anglo-Saxon Hrofescestre, gave the town its present name.

From Rochester we passed by far easier stages than the olden palmers to Canterbury, a much smaller town of much greater ecclesiastical importance, likewise with a name of pleasant etymologic connotation, Cantwarabyrig, city of Kentish men. The modern Canterbury, like that of old time, is still a straggling town built in a narrow strip along a high road that runs at right angles to the river Stour. The cathedral dominates it splendidly, standing in stately magnificence in its grand old close, surrounded, as Hawthorne has said of Peterborough, "by ancient and comely habitations of Christian men." It is a dramatic story they tell of the murder of Becket in this old minster, and a story that after seven centuries still seems vividly fresh as you retrace step by step the course of the martyred archbishop that fateful night, from his entrance into the cloisters, where the lurking knights glimpsed the glint of his ecclesiastical vestments, to the very stone in the great transept where they overtook and slew him. Something of the gloom of that tragedy seems ever since to have shadowed the church, whose castellated stone screen and successive flights of steps add an air of forbidding sternness to the interior. Faith finds it hard to credit the accounts of the fabulous wealth later heaped up by devout pilgrims at the shrine of St. Thomas, "the holy, blissful martyr," but it was evidently great enough to tempt the cupidity of Henry VIII, who thereby profited most unrighteously by his ancestor's crime.

Were it only for its cathedral, Canterbury would still attract pilgrims to-day, but the town is replete with interest apart from that. In the first place, its houses are the quaintest and oldest, and its streets and lanes the narrowest and crookedest, one can find anywhere within equal distance of London. They still show you an old hostelry, on the corner of Mercery Lane, where pilgrims to the cathedral lodged in Chaucer's time; and outside the West Gate another tavern, built in 1403, is still standing, where Sir John Oldcastle, prototype of Falstaff, is reputed to have consumed an intolerable deal of sack. Mercery Lane and Butchery Lane both lead into the Butter Market, where there is a dainty little bronze figure representing the muse of Christopher Marlowe. Christopher was a native of Canterbury, and died at twenty-nine, not the least famous of the men who have distinguished the old town.

Then, too, Canterbury has a multitude of old churches, from St. Dunstan's, — where Henry II doffed his royal robes and whence he went on his knees to the cathedral to do penance for Becket's murder, — to St. Martin's, the mother church of England, built in 680 A.D., and communing still by itself among its yews on a hill apart from and overlooking the town. Then there is the colony of French Huguenot silk-weavers, who came to Canterbury as refugees and since 1576 have exercised the privilege, granted them by good Queen Bess, of maintaining their French church and services in the crypt of the cathedral. Their descendants still continue their weaving trade in a moss-grown old building overhanging the river and bearing in one gable the laudable motto,

> "Fair Warp and Fitting Woof
> Weave a Web that Bideth Proof."

The river Stour runs with affectionate intimacy in and through the town, under old bridges, past garden walls whose luxuriant flowers trail in its waters, under creaking mills whose wheels it still obligingly turns. If there were a pagan tutelary deity of Canterbury, it ought to be the river-god of the Stour. And finally some confluents join it and it broadens out and babbles away serenely through hop-fields and sunny meadows. There is pleasant driving everywhere about Canterbury. One day we went to Harbledown, the last station of Chaucer's pilgrims before they reached their goal. The village must look exactly as it did in his time, and there is still the church of an old Hospital of St. Nicholas, founded by Archbishop Lanfranc for lepers, and now an almshouse for old poor men.

Canterbury also possesses another hospital, the Kent and Canterbury Hospital, a genuine medical institution, founded in 1793, and built to accommodate 104 patients, half medical, half surgical, though it now seldom has more than 80, owing to the establishment of hospitals in other larger and more rapidly growing cities of the county. It has roomy, comfortable wards, a large, modernly equipped operating room, and a pathologic laboratory far surpassing in size and convenience that of several hospitals in Boston. An out-patient department is maintained, and there are two residents, a physician and a surgeon. The latter most courteously showed us about. Among other things of professional interest, we saw a case of extreme microcephalus in a baby two weeks old, and another baby of three weeks with a large lumbar spina bifida, hydrocephalus and a deficiency of cranial bone such that the anterior and posterior fontanelles were merged into one, and practically the entire top of the cranial vault was membranous. This baby also had bilateral extreme talipes valgus.

The spacious, old-fashioned buildings of the Kent and Canterbury Hospital are erected, perhaps with a certain appropriateness, on an old cemetery once belonging to St. Augustine's Priory, a religious foundation which, with its abbey and conventual buildings, was formerly the rival of the cathedral monastery, but gradually fell into decay. A modern missionary college is now established on the site of this priory, and the hospital stands where the old monks were once laid in God's acre. Many melancholy ruins of the old abbey and buildings have been excavated in the garden of the present college. Canterbury is rich in things old and new, and the memories and tangible relics of the old persist harmoniously to be the glory and charm of a later age.

So from Canterbury we came to Dover, and are camped once more by the unvintaged sea. The "old Lord Warden" still stands sentinel by the harbor, and Dover cliffs are still white and still bare their chalky flanks to the dash of the surge. This afternoon we walked from Dover Castle, that crowns the eastern heights, to Shakespeare's Cliff on the west, which still

> "O'erhangs and jutties his confounded base,
> Swill'd with the wild and wasteful ocean,"

as fearfully as in the days of Lear or Harry of Monmouth. It is good to hear again the crisp rattle of pebbles in the undertow on the shingle, and the long, low roar and boom of breakers against the shore, and to see at night the steady flashing of "the coastwise lights of England." To-morrow we are again aboard and off to foreign fields, like

> "Palmers for to seeken straunge strondes
> And ferne halwes couthe in sondry londes."

Medicus Peregrinus.

RECORD OF MORTALITY

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUG. 10, 1910.

GUITERAS, G. M., surgeon. Granted four days' leave of absence from Aug. 9, 1910.

STIMPSON, W. G., surgeon. Granted twenty days' leave of absence from Aug. 11, 1910.

NYDEGGER, J. A., surgeon. Granted three days' leave of absence from Aug. 9, 1910.

BLUE, RUPERT, surgeon. Granted eight days' leave of absence from Aug. 7, 1910.

MOORE, DUNLOP, passed assistant surgeon. Granted fourteen days' leave of absence from Aug. 10, 1910.

FOX, CARROLL, passed assistant surgeon. Relieved from duty in the Hygienic Laboratory and directed to proceed to Manila, P. I., and report to the Chief Quarantine Officer for duty. Aug. 5, 1910.

VOGEL, C. W., passed assistant surgeon. Granted fifteen days' leave of absence from Aug. 10, 1910.

GLOVER, M. W., passed assistant surgeon. Leave of absence for ten days from July 25, 1910, amended to read three days from July 25, 1910.

BAHRENBURG, L. P. H., passed assistant surgeon. Granted six days' leave of absence from July 26, 1910, on account of sickness.

ASHFORD, F. A., passed assistant surgeon. Granted one day's leave of absence, July 30, 1910, on account of sickness.

CLEAVES, F. H., acting assistant surgeon. Granted six days' leave of absence from Aug. 1, 1910.

DEERHAKE, WM. A., acting assistant surgeon. Granted five days' leave of absence in July, 1910, under paragraph 210, Service Regulations.

ELFERS, J. C., acting assistant surgeon. Granted thirty days' leave of absence from Aug. 8, 1910.

HART, GEORGE G., acting assistant surgeon. Granted twelve days' leave of absence from Aug. 18, 1910.

HORNING, HENRY, acting assistant surgeon. Granted seven days' leave of absence from Aug. 3, 1910, under paragraph 210, Service Regulations.

MCLARTY, A. A., acting assistant surgeon. Granted ten days' leave of absence from Aug. 1, 1910.

ONUF, B., acting assistant surgeon. Granted eight days' leave of absence from Aug. 16, 1910.

RICHTER, H. C., acting assistant surgeon. Granted thirty days' leave of absence from Aug. 1, 1910.

RUSH, JOHN O., acting assistant surgeon. Granted fourteen days' leave of absence from Aug. 10, 1910, with pay, and four weeks' leave of absence from Aug. 24, 1910, without pay.

SAVAGE, WALTER L., acting assistant surgeon. Granted thirty days' leave of absence from Aug. 12, 1910.

SCHWARTZ, LOUIS, acting assistant surgeon. Granted seven days' leave of absence from Aug. 8, 1910, under paragraph 210, Service Regulations.

STEVENSON, J. W., acting assistant surgeon. Leave of absence for thirty days from Aug. 3, 1910, amended to read thirty days from Aug. 8, 1910.

STEWART, W. J. S., acting assistant surgeon. Granted one month's leave of absence without pay from July 23, 1910.

TOWNSEND, W., acting assistant surgeon. Granted eight days' leave of absence from July 28, 1910.

WALLACE, C. R., acting assistant surgeon. Granted fourteen days' leave of absence from Aug. 22, 1910.

RYDER, L. W., pharmacist. Granted one day's leave of absence, Aug. 6, 1910, under paragraph 210, Service Regulations.

MORRIS, G. A., pharmacist. Granted twenty-three days' leave of absence from Sept. 6, 1910.

BIERMAN, C. H., pharmacist. Leave of absence for thirteen days from July 26, 1910, revoked.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING AUG. 13, 1910.

LUMSDEN, G. P., medical inspector. Detached from the Naval Recruiting Station, Chattanooga, Tenn., and directed to wait orders. Aug. 5.

TOLFREE, H. M., passed assistant surgeon. Detached from the Naval Recruiting Station, Cleveland, Ohio, and ordered to the Naval Recruiting Station, Chattanooga, Tenn. Aug. 5.

Orders issued by commander-in-chief of Asiatic Fleet:

AMES, M. H., passed assistant surgeon. Ordered to duty at the Naval Hospital, Olongapo, P. I.

HIGGINS, S. L., passed assistant surgeon. Detached from the "Mohican" and ordered to the "New York."

DOLLARD, H. L., assistant surgeon. Detached from the "Relief" and ordered to the "Charleston."

GUEST, M. S., surgeon. Ordered to the Navy Yard, Pensacola, Fla., when discharged from treatment at the Naval Hospital, Las Animas, Colo. Aug. 6.

FITTS, H. B., medical inspector. Detached from the Navy Yard, Pensacola, Fla., and ordered to Washington, D. C., for examination for retirement. Aug. 9.

TOLFREE, H. M., surgeon. Commissioned surgeon from March 24, 1910. Aug. 11.

ALLEN, A. H., passed assistant surgeon. Detached from duty with the Naval Rifle Team of 1910 and ordered to duty at the Naval Hospital, Navy Yard, New York, N. Y. Aug. 11.

HIGGINS, S. L., passed assistant surgeon. Commissioned passed assistant surgeon from Nov. 12, 1909. Aug. 11.

SOCIETY NOTICE.

AMERICAN ASSOCIATION OF CLINICAL RESEARCH. — The second annual meeting of the American Association of Clinical Research will be held in Boston on Sept. 28 and 29, 1910.

RECENT DEATH.

COLLAMORE, FRANCIS, M.D., M.M.S.S., Retired, died in North Pembroke, Aug. 18, 1910, aged eighty-four years.

THE RESULTS OF ONE HUNDRED AND SIXTY-EIGHT OPERATIONS FOR HERNIA.

BY CHARLES L. SCUDDER, M.D.,

Surgeon to the Massachusetts General Hospital; Lecturer on Surgery, Harvard Medical School, Boston, Mass.

I WISH to describe my interpretation of the Bassini operation for inguinal hernia; to record the results of operations for inguinal hernia by this method; to report conditions existing following operations for the repair of other forms of hernia; to state certain important facts concerning hernia.

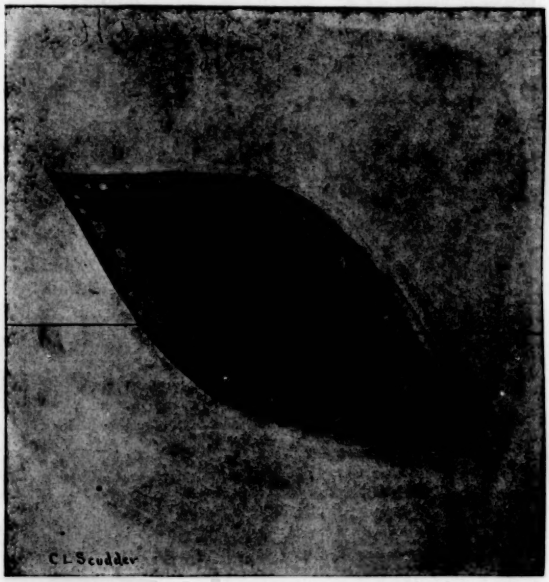

FIG. 1. Oblique incision through skin and superficial fascia down to the fascia of the external oblique muscle. Note the external abdominal ring made apparent by slight bulging caused by full hernial sac.

The accompanying drawings were made for me from studies of the anatomical findings at operations for hernia. These drawings illustrate the essential details of Bassini's operation for inguinal hernia. The operation is as follows:

A straight and obliquely placed incision is made parallel to and one finger's breadth above Poupart's ligament sufficient in length to expose readily the position of the internal and external abdominal rings. The few bleeding vessels are clamped and immediately ligated. The external abdominal ring is exactly developed by a few strokes of the knife and blunt dissection. (Fig. 1.)

The external oblique fascia is divided parallel with its fibers and freed by blunt gauze dissection from the parts beneath for about two fingers' breadths from the cut edges. The lower border of the internal oblique muscle, the sac of the hernia, the cord covered in part by the cremaster muscle and fascia are thus exposed to view. (Fig. 2.) The cremaster muscle may be well developed, as is indicated in the drawing, or it may be poorly developed and appear as a thin fascia with a few muscular fibers scattered through it. When the muscle is well developed, it may be utilized in closing the abdominal wound (Halstead), as is here illustrated.

The cremaster is split parallel with its fibers and separated from off the sac and cord and the sac developed by blunt dissection with fingers and gauze. The sac lies anteriorly to the cord and may be found high up near the situation of the internal ring. The sac appears as a whitish membrane when first discovered. The sac is thus more clearly exposed to view. The sac is held by dissecting forceps and opened by knife or scissors. (Fig. 3.) The sac is emptied of its contents. This step is often facilitated by the Trendelenburg position, complete anesthesia of the patient and a gauze sponge thrust into the sac and cautiously withdrawn. If any intra-abdominal organ (intestine, omentum, bladder) is found adherent to the interior of the hernial sac, it should be carefully freed and all bleeding checked.

If the sac is a thin and short one, not extending to the bottom of the scrotum, after it is opened, upon introducing the finger within it, the sac may readily be separated from the surrounding tissues of the cord and isolated. If the sac cannot be thus readily stripped from the surrounding parts, then after opening the sac, as shown in the drawing, it is divided transversely down to the cord and its vessels. The line of posterior division of the sac over the cord is indicated in Fig. 4. After dividing the peritoneum, the separation of the cord from the sac is very greatly facilitated by blunt sponge dissection. The proximal part of the sac is isolated (*a*) from the cord and (*b*) from the abdominal muscles (the internal oblique, conjoined tendon) in order to facilitate the placing of the peritoneal suture. It is important to make the isolation of the neck of the sac complete in its whole circumference so that the subsequent suture will be an effectively placed one.

The commonly used purse-string suture, even if applied with transfixion of the neck of the sac, may slip. This occurred to me some years ago. It unfortunately happened before the outer wound was closed, so that a secure suture was immediately placed. Since that time I have used the suture illustrated in Fig. 6. When the sac is very thin walled, a purse-string suture securely applied will serve every purpose. The distal portion of the sac [the scrotal part, if such exists (Fig. 5)] it is well to remove. If it is left *in situ*, no suture is taken in its mouth. The cavity of this sac is probably completely obliterated. If the distal portion of the sac is undisturbed, its interior should be thoroughly wiped with gauze to facilitate its obliteration by the process of repair. I have never seen a hydrocele or cyst follow this method of treating the undissected distal portion of a thin hernial sac.

Traction downward upon the proximal portion of the hernial sac and retraction of the tissues (internal oblique, cremaster, etc.) at the upper angle of the wound, together with traction downward upon the cord, facilitate suturing the peritoneum. (Fig. 6.) I have used the continuous loop or hemstitching suture taken with No. 1 chromic gut and a curved needle. (Fig. 6.)

FIG. 2. Oblique incision in line of fibers of the external oblique fascia. External oblique fascia freed from parts beneath. Note fibers above of internal oblique, conjoined tendon, below well-developed cremasteric fibers, bulging sac of hernia, cord showing at inner angle of wound.

The cord and distal portion of the sac, if left, are now lifted by blunt dissection from their bed, if it is decided to transplant the cord, and are together held aside. (Fig. 7.)

The next sutures are placed as indicated in Fig. 7. It is well to avoid including within the suture the ilio-inguinal and the genital branch of the genito-crural nerves below the lower border of the internal oblique. I always place one or two sutures external to the spot where the cord comes through the peritoneum (Fig. 7) and superficial to the suture of the neck of the sac. These two sutures

precludе the possibility of a recurrence of the hernia at this particular place. The remaining sutures are placed so as to lie beneath the uplifted cord. These interrupted sutures include the lower border of the internal oblique and conjoined tendon, the cremaster muscle and fascia and Poupart's ligament. (Fig. 7.) The sutures are tied securely without constricting too severely the muscular tissues. (Fig. 8.)

The cord is placed upon the tissues approximated by this series of sutures, and the external oblique fascia is closed over the cord by a continuous chromic catgut suture, taken as illustrated in the drawing (Fig. 9), with a loop or hemstitch. The fascia is thus not only approximated, but there is a definite overlapping or

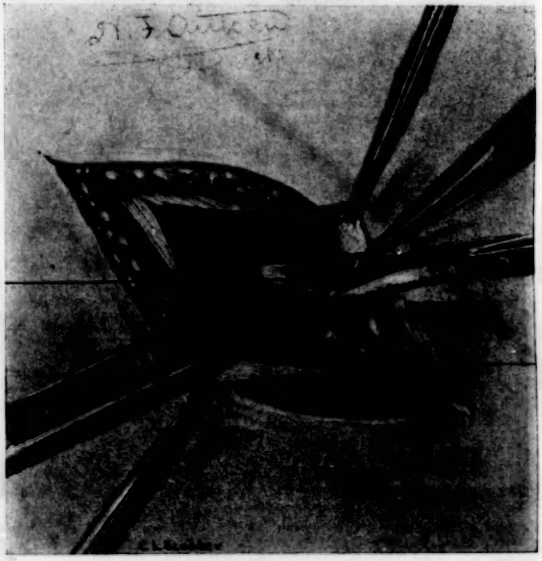

Fig. 3. The sac of the hernia has been isolated sufficiently and raised by forceps. Note scissors opening the sac, cord in lower angle of wound.

coaptation of the two layers of fascia as by the mattress suture. Mayo has called attention to the security of the mattress suture employed in the transversely overlapped fascia in umbilical hernia. Halstead has emphasized the firmness of a wound closed by the mattress suture in cases of inguinal hernia.

The superficial fascia is next approximated, and with it the subcutaneous fat tissue, by interrupted fine No. 0 catgut sutures. The skin is closed by silkworm gut, either cutaneously or subcutaneously placed. All blood and moisture are carefully wiped from the suture creases and skin. A dry sterile gauze dressing fastened with collodion is applied.

I think no especial dressing of a wound of the kind described above has any advantages over the simple dry sterile gauze. I have seen used, silver foil, ointments, pastes and powders. I think that the two factors, other things being equal, which assist or favor the healing of a hernial wound are absolute hemostasis and a minimum of operative trauma (by traction, etc.) to the skin edges and to the other tissues of the wound. Trauma to the skin may be avoided by an ample cutaneous incision.

So important is absolute hemostasis that I not only ligate every tiny bleeding point in the wound, but I apply a ham splint to the leg of the operated side, that the spica bandage applied to hold the dressing may exert a maximum of pressure upon the wound during the first twelve or twenty-four hours. The splint is then removed. There is no pressure exerted upon the region of the groin by a spica bandage if the patient is permitted to flex the knee of the bandaged side. A broad band of adhesive plaster is used by some operators to secure the dressing and maintain pressure.

In enumerating the facts which seem to me important in the operation for the cure of an inguinal hernia, I would include the following: An ample cutaneous incision; absolute hemostasis; an anatomical dissection of the parts concerned, so that every structure is clearly recognized; the complete isolation of the neck

or abdominal portion of the sac; the complete emptying of the sac of both adherent and non-adherent contents; the suture of the hernial sac at the level of the peritoneum of the anterior abdominal wall; the exact suture of the abdominal wall superficial to the peritoneum, including always one or two sutures placed over and above the sutured sac; the minimum of trauma to the cord.

In all ordinary cases of inguinal hernia, I have found this method of exposure and suture of the hernial sac and the method here described of repair of the abdominal wall satisfactory. I have seldom found it necessary to excise the veins of the cord. I have occasionally in children not transplanted the cord. I have utilized the fascia of the rectus abdominis a few times to reinforce the abdominal wall above the inner end of Poupart's ligament, as described by Halstead.

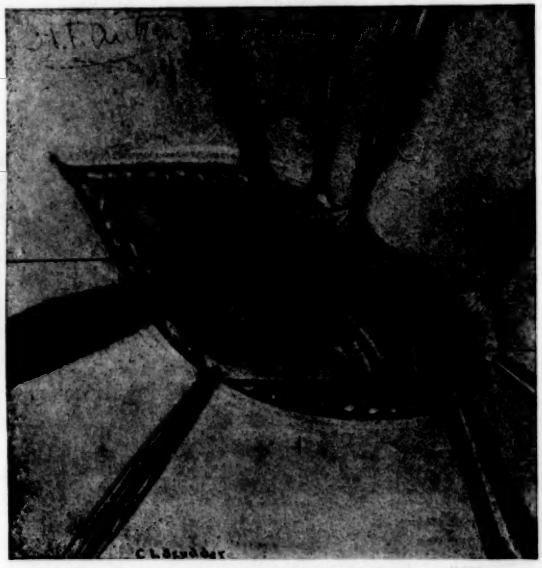

FIG. 4. The sac of the hernia has been opened. Note the interior of the sac leading towards peritoneal cavity above and to the scrotum below. Note the cord posteriorly to the sac and the dotted line across the sac indicating the line of section for further isolation of the peritoneum.

RESULTS FOLLOWING OPERATION FOR HERNIA.

I wish to report 244 operations done by me for herniæ of all kinds. There have been no deaths following operation in uncomplicated cases. The only deaths were in the strangulated group. There were 25 cases of strangulated hernia; 10 of these died; 3 were inguinal, 1 was ventral, 1 was femoral, and 5 of the 10 fatal cases were umbilical. These 10 deaths make a mortality of 40% in the strangulated group.

I have succeeded in obtaining the present condition of 158 of these cases. Of the 158 operations, 143 wounds are solid and without recurrence. That is, 90.6% of the cases operated upon in whom the returns were known were cured.

There were 165 cases of *inguinal* hernia; 53 cases did not report; 3 strangulated cases died; 10 of the 109 cases in which the end result is known recurred. That is, 90.9% of the inguinal group were known to be cured.

There were 27 cases of *ventral* hernia; 11 did not report; 1 of the cases recurred; 1 died of strangulation; 14 of the cases in whom the end result was known were all right. That is, 93⅓% of the cases reported were cured.

There were 13 *umbilical* cases. There was no report from 3 cases. Of the remainder, 5 died of strangulation; 5 had no recurrence.

There were 5 *epigastric* herniæ. All of these reported, and each case is well.

There were 2 *congenital* cases, each of which died. The ages of the deaths of these 2 congenital cases were four hours and twenty-four hours respectively.

It will thus be seen after a careful analysis of the returns from these cases of herniæ that there are comparatively few recurrences following the

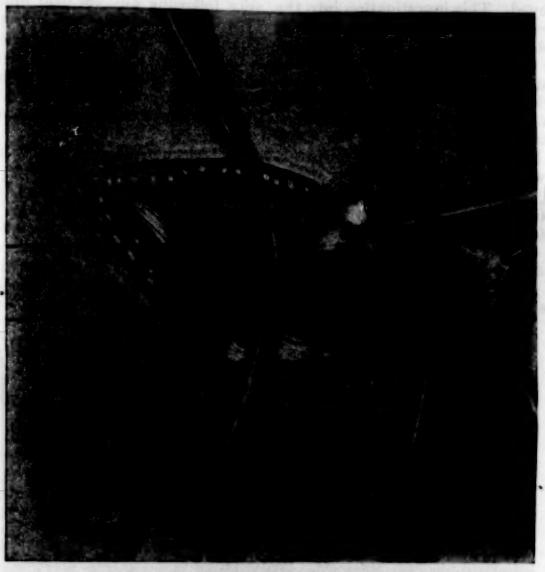

FIG. 5. The peritoneal portion of the hernial sac has been completely isolated; likewise the scrotal portion. Traction towards the symphysis pubis upon the peritoneal upper part of the sac facilitates proper placing of the sutures.

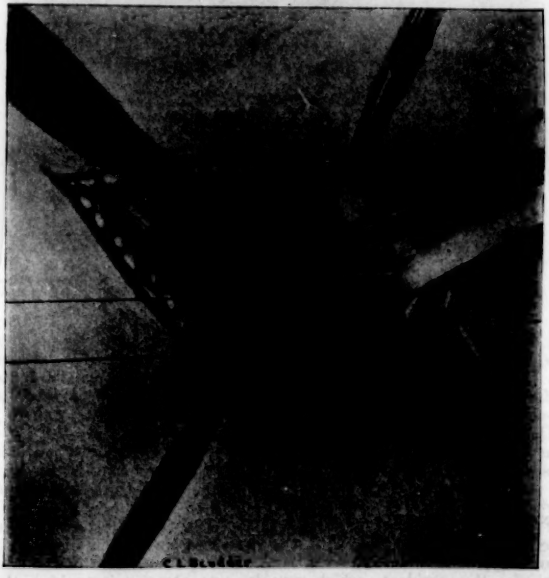

FIG. 6. The suture is being taken through and across the neck of the sac. Note retractor keeping internal ring region well in view. Note lifting of cord by gauze tape.

procedures employed. This investigation into the condition of these hernia cases was undertaken primarily to determine whether any material change might be necessary in the technic of the operation to secure better results. In analyzing the 10 cases in which recurrence is known to have occurred in the inguinal hernia group, conditions were present which precluded, perhaps, the possibility of cure. In certain (2) of these cases a chronic cough which had persisted for years contributed to the recurrence. One case was a strangulated case, and it is very likely that the operation was done with such haste on account of the condition of the patient that the technic was not as satisfactory as it might have been. In the other 7 cases there is no explanation apparent for the recurrence.

FIG. 7. Cord well raised, with all cord structures, from inguinal canal. Note suture placed beneath cord passing through conjoined tendon cremaster and Poupart's ligament. Note separation of inner part of divided fascia of external oblique.

I think it is fair to say that the operation described above as the Bassini operation for inguinal hernia is most satisfactory and that if carefully performed gives at least a cure in 90% of the cases and possibly in 95% (Coley) of the cases. There was no mortality attending these operations for hernia. Certain of the strangulated cases recovered. Ten strangulated cases died.

CERTAIN FACTS OF IMPORTANCE.

One should consider in connection with the question of mortality, and when advising an operation for hernia, the accidents which may arise following any surgical operative procedure. There is, of course, a risk from the anesthetic. There is a risk from possible pneumonia. There is a risk from possible embolism or from sepsis, but these risks must be taken and are to be disregarded under modern careful technic in the question of a lesion so important as a hernia.

There are a number of hernia operations described, but if each is carefully analyzed it will be found that all of the satisfactory procedures are based upon the same fundamental principles. Every operation for hernia presupposes the existence of a pouch of peritoneum into which the abdominal viscus protrudes. The presence of this peritoneal pouch is a constant invitation to the contained viscus, whether it be intestine or other organ, to protrude. Until this pouch is completely obliterated, the hernia cannot be cured. The Bassini operation as described above seeks to obliterate the hernial peritoneal pouch on a level with the anterior abdominal wall so as to efface all evidence of a pouch.

After the peritoneal pouch is eliminated, the further steps in the technic of any good hernial operation consist in a firm closure of the muscular and fascial abdominal wall. The method employed in the operations here reported was that described above.

The *spermatic cord* in the adult is best treated by transplanting it to beneath the layer of the

Fig. 8. Sutures above and below the cord tied excepting two.

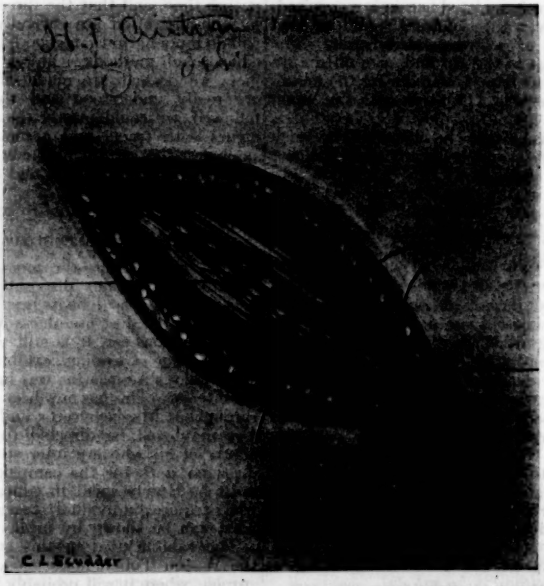

Fig. 9. Suture of the external oblique fascia above the cord.

external oblique. In children it does not seem necessary to transplant the spermatic cord. In certain cases in adults I have not transplanted the cord and the results have been satisfactory.

There are very few cases indeed in which a resection of the *spermatic veins* is a necessary step in the operation for hernia. I should state the necessity for operation in this way: If there exists in any case of hernia a good-sized varicocele, it would be wise to remove these veins not only for the cure of the varicocele, but to obtain greater security in the wound.

If there is present upon the side of the hernia an *undescended testicle*, I believe that, unless there is some contra-indication, the removal of the testicle with ligation of the cord upon a level with the parietal peritoneum is indicated.

I believe that there are few cases in which the general anesthesia secured by ether will not be satisfactory. Local cocaine and spinal anesthesia should be reserved for cases too ill to be etherized, and for the aged and those with a tendency to chronic bronchitis. In certain strangulated cases where the patient is very ill a local or spinal anesthesia may be indicated.

It seems to me that it is unwise to operate upon infants under three years of age for hernia, and in the very aged operation is often contra-indicated. These two extremes of life offer the chief exceptions to the operation for inguinal hernia. The operation for hernia is a safe operation.

It seems to me very important to emphasize the fact that an immediate operation should be done when a strangulated hernia is recognized. No taxis, not even the slightest, should be used in the presence of a strangulated hernia. The danger of damage to the gut and even of rupture of the gut and the danger of reducing the hernia *en bloc* is considerable. Delay in operating upon a strangulated hernia is unwise. Taxis of a strangulated hernia may be attended by such dire consequences that I believe it should almost never be employed.

EDUCATIONAL METHODS IN THE ANTI-TUBERCULOSIS CAMPAIGN.*

BY JOHN B. HAWES, 2D, M.D., BOSTON.

THE two most important factors in the campaign against tuberculosis are:

(1) The isolation of the advanced consumptive, thus preventing the spread of the disease, and

(2) The education of the public and of the medical profession in regard to the nature of the disease, thus bringing about its early detection and treatment. This at least is the attitude of Massachusetts toward the tuberculosis problem.

The new sanatoria recently opened at North Reading, Lakeville and Westfield are primarily for the segregation and isolation of the advanced consumptive.

The medical profession of the state, as represented by these Associated Committees, in conjunction with the Massachusetts Commission on Hospitals for Consumptives, the Health Inspectors of the State Board of Health and the numerous local anti-tuberculosis associations, are carrying on a campaign of education. The various methods employed, and the relative advantages and disadvantages of each, it is the purpose of this paper to discuss.

For many years we have been trying to educate the public in regard to tuberculosis. Ten or fifteen years ago, however, it was only the consumptive public whom we tried to educate, and that only in a desultory way. At that time, at any out-patient department, as, for example, at the out-patient department of the Massachusetts General Hospital, a consumptive coming for advice was told to take the examination for the Rutland State Sanatorium. If for any reason he was unable to do this, or if he was not accepted at this institution, he was handed a tract elaborately printed in whatever language he spoke, in which directions were given as to how he should live. "Take this tract," said the doctor, "put it on your bureau or wall at home, read it and learn it, and by following its directions you will get well." I am very doubtful if this method did much or any good. Indeed, I think it did harm in that it filled patients with a false sense of security in regard to themselves and the disease. Education to really educate must be more effective than this. One can easily prescribe an appropriate drug for a given ailment, but unless one sees that it is given in the proper doses, at the proper time, and that the directions in regard to its administration are carefully followed out, it will do more harm than good. It is the same with educational methods — unless we see that the facts we present are made effective, that they are really understood and that directions are followed, we could plaster the walls of our tenements with tracts and accomplish nothing. I shall describe certain methods which have been found effective for adults and for children.

I. EDUCATIONAL METHODS SUITABLE FOR ADULTS.

(*a*) THE TUBERCULOSIS EXHIBIT.

This was perhaps the most effective method of education at our disposal. In this state I believe that it has done its best work and that the time of its greatest usefulness is past. In certain localities, however, it is still very valuable.

The large traveling exhibit of the Boston Tuberculosis Association was invaluable in arousing interest. This has now been fairly well aroused throughout Massachusetts, and our present energies may well be directed toward guiding the efforts of all who are interested and anxious to do some work for the campaign. These efforts must be largely spent in educating the ignorant, who require individual teaching rather than what can be shown by means of large exhibits.

The exhibit used in this state, managed by the Boston Tuberculosis Association, is now in storage, where it will probably be kept for a year

* Read before The Massachusetts Medical Society, June 7, 1910.

or more, after which it will doubtless be sent on another tour. In the meantime I strongly urge the formation of small, compact exhibits, such as that which has been prepared for school purposes, to be described later. Such small exhibits can be made at little cost, require no attendant to travel with them, and will be of the greatest assistance as a means to illustrate talks on health and hygiene, as well as on tuberculosis, given in shops, factories or before labor unions, women's clubs or other small groups of people who can be talked to in an informal way. Such an exhibit, put up in a prominent place in a store or factory, would, I believe, do a great deal of good if the attention of the employees was called to it and a few demonstrations given as to what it meant.

The school exhibits, which I shall describe later in detail, are not designed to fill the need for such an exhibit mentioned above, but merely to serve as examples, which tuberculosis associations and school committees can obtain at a low price.

(*b*) PRESS ARTICLES.

At the offices of the State Tuberculosis Commission, 3 Joy Street, Boston, every two weeks a short article in regard to tuberculosis is sent out to about two hundred newspapers in Massachusetts. These articles are prepared either by the National Tuberculosis Association or by the Commission. They are given a wide circulation. Such a method as this has the advantage of reaching a very great number of people at a very slight cost. The exact amount of good which it does it is hard to estimate. By itself I do not believe that this method of education will accomplish much, but where any anti-tuberculosis campaign is active, and as a part of such a campaign,— by pointing out to every one what is being done, and how and where information may be obtained, etc., — I believe that press articles will do much good. Salem has carried on this method of education in a most effective way, combining articles of general educational value with those of general interest. Gardner is following suit with a series of articles on tuberculosis which appear in the local paper. In scattered agricultural communities, where it is very hard to get people together in large numbers for lectures, exhibits, etc., the public press should be used far more than it now is for educational purposes. In such districts as Barnstable, etc., the daily or weekly paper is read with the greatest of care, advertisements and all, and each item is discussed at length in the home. Short, breezy articles on health, hygiene, fresh air, etc., will receive careful attention and do a great deal of good. All such articles should be written in what is called "newspaper" or "journalistic" style; if not, either the editors will not publish them, or, if published, they will not be largely read.

(*c*) LECTURES, TALKS, ETC.

The amount of good to be accomplished by lectures, talks, etc., depends largely on the speaker's ability to size up his audience and to talk in a language suited to its needs. In Boston many young physicians are called upon to address various labor unions, groups of factory employees, etc., on the subject of tuberculosis. Many such talks, given by young hospital graduates, while they deeply impress the listeners with the learning of the doctor, convey very little information to them. It is hard in a lecture of this kind to put things in simple enough terms. Such talks should be absolutely informal and should be short — not over fifteen or twenty minutes. The speaker should impress a few facts upon his hearers and see that these facts are clearly understood, rather than attempt to give a general sketchy outline of the whole subject. He should drive home his facts by local allusions. If he is talking to the Cigar Makers' Union, the dangers of this occupation should be emphasized; if he is addressing a Bakers' Benevolent Society, the need of cleanliness, etc., should be dwelt upon.

Lectures to women's clubs offer great opportunity to arouse enthusiasm and awaken active interest. Such audiences are usually of a rather intelligent order, and in addressing them one need not "talk down" to any very great degree. The majority of women's clubs need waking up. A purely scientific paper will not do this. Women are at heart sentimentalists, and the recital of a few striking examples of harm done by neglect or ignorance of this disease will do more good than many facts. A description of active work carried on by other women's clubs will stir up local interest and help to get things done. If I am speaking in Lawrence, for instance, I am very apt to describe in glowing terms how the Quincy Women's Club raised the money to hold the tuberculosis exhibit, formed an anti-tuberculosis association and helped to establish a day camp. Most important of all, no speaker should conclude his address before a woman's club without mentioning one or two lines of practical work which such an organization could carry on and which he has found out beforehand are much needed. Lectures in churches and before tuberculosis associations should be of a similar nature. I believe no talk should be over thirty minutes in length. Lantern slides, given after the talk, with a brief description of each, pointing out what it teaches and how it applies, are of the greatest help. A sense of humor judiciously used will help to maintain interest in what at best is a most serious subject. At the end of many talks which I have given, the presiding officer usually states that the doctor will be glad to answer all questions, etc. An embarrassing period of silence almost always follows, unless some anxious parent arises to ask what should be done in the case of Nellie or Johnnie. I well remember one such instance, when a most charming old lady asked me whether or not I advised young ladies to use silk underwear. Unless certain people are prepared beforehand to ask intelligent questions it is usually far better to omit this so-called "discussion."

(*d*) CARDS, PLACARDS, ETC.

Prominent anti-spitting signs of course accomplish some good. I do not believe they accomplish very m ch, however, unless once in a while the board of health of the community in which these signs are posted enforces the law, causes a few arrests to be made and publishes articles in the local press explaining why this is wise, proper and necessary. Posters, circulars, etc., giving facts in regard to tuberculosis, without any local information, I do not believe accomplish much. Large posters, such as are used in New Bedford, telling people where and when they can be examined and secure treatment, are really valuable. Attractive calendars, with pictures of Rome, Venice, Syria or the home country of the people for whom they are intended, with information in regard to tuberculosis and the local dispensary, etc., will be hung up in every home and will be noticed. Such calendars as gotten out by the New York Charity Organization Society and the Boston Tuberculosis Association are not expensive, costing approximately $30.00 to $35.00 per 1,000. Elaborate pamphlets, such as that printed by the Illinois State Board of Health, which is perhaps the best of its type, and others as printed by our board of health and the tuberculosis association, etc., will do good only among the more intelligent classes, and will hardly reach those where the need of such information is most urgent. They are also more expensive.

At the Commission offices we have recently prepared a small folder of stiff pasteboard to be placed in the pay envelopes of employees in large factories and other concerns. Ten thousand of these were prepared for the General Electric Company of Lynn. Brockton, Pittsfield, Clinton, Salem, Fitchburg and other places have adopted this idea. In addition to certain information in regard to tuberculosis, the address of the local dispensary is given and the days and hours when patients can be examined and secure treatment are stated. Such cards cost $24.00 per 5,000; $43.00 per 10,000. Information in regard to these can be secured at the Commission office. In Fall River they have placed short notices in regard to tuberculosis inside the covers of the school books. This is a cheap and efficient method of calling the attention of the children to the subject.

(*e*) THE TRAINED NURSE AND SOCIAL WORKER.

As was stated in the beginning of this paper, it is the trained nurse or social worker who is to make these educational methods effective. Despite some pessimistic reports which reach us from Baltimore, where apparently they have come to the conclusion that the trained nurse cannot accomplish very much in the homes, I firmly believe, and I think we all believe, that it is the trained nurse or trained social worker, seeing patients in their homes and in the workshop, who is the great factor in any educational campaign. A splendid example of such an educational work is that now being carried on at the immense factory of the Dennison Manufacturing Company in South Framingham. During the past year this concern has employed a nurse who devotes all her time to seeing that the working and home conditions of the employees are satisfactory. She takes the sick to the doctor or to the hospital for treatment; those who are run down or in poor health she studies, helps and advises, and, most important of all, she goes into the homes and teaches these people how to live. The good that women can do in this way as nurses, or social workers, or trained volunteer visitors, is enormous. It is limited solely by their number or by the means to pay for their services.

II. EDUCATIONAL METHODS BEST SUITED TO CHILDREN.

(*a*) THE SCHOOL NURSE.

Here again the nurse is the important factor. Physicians can examine the children, legislatures can pass laws directing that there shall be instruction in tuberculosis, its prevention, etc., teachers can be provided with information on the subject, but unless there is a woman medically trained as regards the disease, socially trained to cope with social problems, and, most important of all, trained or endowed by nature with tact and good sense, little will be accomplished among the children. The importance of this cannot be overestimated. Every one agrees that it is hard or impossible to get adults, particularly among the lower classes, to change their set ideas and methods of living. It is by dealing with the children that we are really going to control tuberculosis, not in this generation, nor in the next, perhaps, but some time in the future. Pittsburg, under the leadership of Dr. Charles William White, is doing this educational work among children in a most effective way. After a great deal of difficulty, permission was secured from the Board of Education and from the boards of control of the different public schools to teach the children in regard to tuberculosis. A trained nurse and social worker was secured and well paid to devote her entire time to going around among the different schools and giving short talks. In taking up this work in any individual school a preliminary meeting was held with the superintendent, teachers and janitors, at which the nurse explained her plans. Next the nurse gave fifteen-minute talks to the children, taking them in small groups, going from classroom to classroom. After school hours the mothers were invited to attend a meeting at the school, where the same subject was gone over from a somewhat different point of view. Later on the children were given an examination or asked to write an essay on what they had learned. The school nurse co-operated with the school physicians and with the parents and children in their homes.

No system quite so elaborate as this has been carried out in this state. On a small scale, however, it has been done. In Canton, for instance,

there is a school nurse who not only gives talks to the children and to the teachers at the school, but follows the children into their homes, becomes well acquainted with the mothers and gives instruction in proper methods of living. The Boston school nurses are doing magnificent work. Without such a school nurse I do not believe that the teachers alone can do very much effective teaching in hygiene and allied subjects. According to Chapter 181 of the Acts of 1908, a law was passed that "in each of the subjects of physiology and hygiene special instruction as to tuberculosis and its prevention shall be taught as a regular branch of study, . . ." etc. In accordance with this act, and at the request of the State Board of Education, a committee of Boston physicians prepared a pamphlet on the subject of tuberculosis, a copy of which was placed in the hands of each teacher in the state. In comparatively few places was there a school nurse to give this instruction or to make this law effective, and, as a result, I do not believe that this law, beneficial and wise as it was, has as yet accomplished very much. The majority of teachers are already overworked and can hardly be expected, either on account of lack of time or lack of training, to give this instruction; it is the school nurse who can do this, and it is the appointing of such nurses which will prevent this law from becoming a dead letter, as in many instances it now is.

(*b*) School Tuberculosis Exhibits.

A bill has recently been passed by the legislature, introduced by our Associated Committees, giving an appropriation of $1,000 to prepare small "school tuberculosis exhibits." Such an exhibit will show graphically what tuberculosis is, what it does, how it is spread, how cured, and, most important of all, how prevented. This exhibit, now that the original plates, frames, etc., have been made, can be duplicated for $30.00 to $35.00. Upon request certain frames will be left vacant in order to insert pictures or charts of local interest. It is planned to place such an exhibit as this, as far as can be provided out of our small appropriation, in public schools in the state, and to have it go from classroom to classroom, perhaps remaining some months in one school. It is to be used as a means of illustrating talks given by school teachers, nurses or physicians on health, hygiene, tuberculosis, etc. Our appropriation can only provide us with a small number of such exhibits. It is hoped that school committees and local tuberculosis associations will take up this work and duplicate these exhibits throughout the state. Such an exhibit as this will do a great deal toward making instruction in regard to tuberculosis and its prevention effective.

(*c*) Outdoor Schools, Etc.

The value of the outdoor school or of the "outdoor room," one of which is being arranged for in each public school in Boston, as an educational factor is immense. Parents are bound to be deeply impressed by the rapid improvement in the condition of their children, and the lessons learned at such a school concerning fresh air, good food, cleanliness, etc., are sure to be discussed in the home.

In Cambridge, Salem and elsewhere school children have been given examinations and have written essays on health and hygiene in addition to their regular studies. Such examinations as these, if of a practical nature and supplemented by other means of education, are sure to do good. I recently looked over examination papers written by a child of eleven and a child of fourteen in a Salem school, and I can merely say if the average child knows as much about tuberculosis, or if the answers to the questions represent what the children really know, that in the next generation Salem will have consumption well under control.

III. Indirect Educational Factors.

Among such indirect educational factors may be mentioned the sanatorium and camp, and the tuberculosis class or dispensary. The sanatorium acts in two ways: First, as a striking example to those people in the immediate neighborhood in regard to outdoor life, and, next, by the influence and example of those patients discharged as arrested or cured. This latter factor, however, may work for evil as well as for good. Unless the discharged patient is placed in touch with the local tuberculosis association, dispensary or nurse, there is grave danger of a rapid relapse, which will place this example of the value of the sanatorium treatment in a most unfortunate light. There is no need of emphasizing the good done in an educational way by children or adults attending a properly conducted tuberculosis class or dispensary.

Last I wish to speak in regard to a very much-neglected educational factor — the influence of the physician himself upon his patients and upon his friends. In spite of the active work being done in Massachusetts, a state which stands foremost in this country in the anti-tuberculosis movement, there are far too many physicians who take no active part in this campaign. In many instances this is due to the burden imposed by an active practice; in many others, however, it is due to the belief that this work is already in the hands of a few physicians who can do it all and who do not need any help. In Boston, for example, it has been only with the greatest difficulty that young physicians have been secured who are willing to give talks to the various labor unions and other organizations which are constantly asking for speakers. Wherever the tuberculosis exhibit is held the work is usually done by one or two active men — the bulk of the profession sits back and waits to see if it is going to be a success before taking part. The fact that not even 50% of the patients being treated at the Rutland State Sanatorium, an institution which was primarily for incipient cases, are of the incipient class demonstrates only too clearly the need of education in the medical profession as to what constitutes an early

diagnosis. The truth of the statement that "successful treatment ends where physical signs begin" is far too little recognized. Physicians are waiting month after month for tubercle bacilli to appear in the sputum before they tell their patients that they have consumption. In many communities it seems as if the average private citizen were more familiar with the general subject of tuberculosis and its prevention than the medical profession; it is undoubtedly true that the active workers in many tuberculosis associations are not physicians, but lay men and women. The physician as an educational factor in this campaign in Massachusetts is not what he should be; we must realize that education is needed among ourselves as well as by the general public.

The final point which I should like to bring out is this: that whichever of these educational methods any community takes up, whether it be by giving a series of lectures, or pay envelope cards, or school tuberculosis exhibits, or what not, the work cannot be well done and cannot accomplish what it should unless it is backed up and made effective by the efforts of a tuberculosis nurse or social worker. This is the real key to successful education in this anti-tuberculosis campaign.

Discussion.

Dr. Eugene A. Darling: I have not much to add to what Dr. Hawes has already said. I think in Cambridge our experiences bear out to a very large extent what he has outlined. We have tried all the methods he has mentioned, and we find that his concluding remark is true, — that there is a very distinct difference between the kind of work which can be done by the true social worker and the nurse. The nurse gives her chief attention to the sick patient, dealing with her comfort. On the other hand, the social worker takes a much broader view of the case. A variety of problems are presented to her that she is competent to handle because of her experience. We find that the nurse, as a rule, is not able to handle the larger problems, and yet she can do the actual individual work even better than the social worker. In Cambridge the work goes on much better if the social worker does not have to think of the nursing, and, on the other hand, the nurse does her work better if she does not have to think of the social part of the work.

In Cambridge, whatever work has been accomplished by the society is very largely due to the fact that we have a very competent social worker who has given a great deal of her time to the work. Our association has worked in co-operation with the Visiting Nurses' Association.

The other point I wish to mention is the work in the public schools. Cambridge has made an effort to have the law of 1908 put into operation there. We felt the law was worth trying and a committee from the association held several conferences with the superintendent of schools and, as a result, the following method was adopted of putting the law into operation. It was found that it was better to have the teaching done by the teachers, and yet most of the teachers were unable to give any competent instruction upon this subject of tuberculosis, and, therefore, it was thought best to have several conferences between a physician and the teachers. It was thought that the same instruction would not be desirable for scholars in all the grades. The teachers were divided into three groups. The first group comprised the kindergarten and the primary schools, the second group the grammar schools, and the third group the high schools, and when it became my task to think up what to say to these three groups of teachers, I was very hard put. It was a task of great difficulty indeed, and I do not feel quite satisfied with the result of my effort, but at any rate we did carry out that plan. I advised the teachers of the kindergarten and primary schools to say very little about tuberculosis itself, but to lay great stress upon the hygiene, cleanliness, ventilation, exercise and general topics of that kind, keeping the subject of tuberculosis largely in the background, because the children of that age were not able to understand very much about tuberculosis. I advised the teachers of the grammar schools to give their chief attention to the general topics of hygiene, sanitation, and then to give some general instruction about tuberculosis, talking about the great extent of the disease and in a general way the measures which are employed to combat it. I advised the teachers of the high schools to speak upon the subject of personal hygiene to a greater extent and to apply such methods as were necessary to the subject of tuberculosis. I used the pamphlets established by the State Board of Education, and we used Dr. Clark's book, a very useful book for purposes like that.

I had a chance to test whether the scholars grasped the subject or not by the fact that a friend of mine had a boy in one of the lower grades. My friend said that her boy had come home shortly after one of these meetings full of the subject of tuberculosis. She questioned him a little, and I asked her what he said, and she repeated what was really a very good description of the subject that the boy had grasped. If the children get as good an idea as that, we think the work is well worth trying. We all know that what the teacher says carries the greatest weight. Teachers are ahead of parents. What they say goes, and the children will remember it. It remains to be seen whether the plan will be successful to repeat in future years.

One teacher said he was trying to do as little of this, and keep within the law, as possible. He said, "I do not believe in talking about these things to children because it is a disagreeable subject." I was a little hot in my reply to him. I said, "It is disagreeable because you make it so. It is not more so than a great many other things we have to approach if done in the right way. We must go about it in the right way." He admitted that perhaps that was so. He said he would try to do more in the future.

Dr. J. F. A. Adams, of Pittsfield: The Berkshire committee has spent its chief efforts in organizing local antituberculosis associations. We have one in Pittsfield, one in Great Barrington and one in Adams. They are all doing good work. Each has a visiting nurse. There is also a visiting nurse in Williamstown.

The school children are being instructed. A little girl who is a member of my daughter's Sunday-school class came to supper at my house last week just after the traveling exhibit of the Boston Association had been in Pittsfield. She began to talk about the exhibit which she had been to see, and I found she was very well informed about tuberculosis. I asked her where she had learned this. She said from one of her school books, which she would bring around and show me. She did so, and I found it a delightful little book called "Town and City," with twenty pages on tuberculosis and its prevention. She was in the sixth grade.

Education of adults is less satisfactory. I was told recently of a man who had been at Rutland for some months, and had been discharged with the disease not arrested. When somebody spoke to him about his

careless spitting, he remarked, "I know all about it, and I am going to spit where I've a mind to."

There is one thing which has not been spoken of very much, and I would like to say a word as to the education of the medical profession. There is not sufficient enthusiasm in the medical profession in this work against tuberculosis. A few of the doctors are very much interested, and others are not. I do not know exactly why. What is it? You can all form your own conclusions. It requires a great deal of care and attention, with little or no return, and a busy doctor finds it hard to investigate every case that comes to his office, and a great many cases of slight cough are called "bronchitis" and treated casually. The patient goes away and comes back perhaps in two or three weeks. It is not easy for the doctor to investigate carefully and thoroughly every slight case of cough. His waiting room is full of patients, and he has perhaps fifteen minutes for each. These patients ought to have half to three quarters of an hour. I cannot emphasize too much the importance of this extra care.

There is one way of getting at the doctors. I am one of the committee for preparing questions for the examinations of candidates for membership in The Massachusetts Medical Society, and two of the questions at the last examination were these:

"1. Diagnosis and treatment in a case of incipient pulmonary tuberculosis.

"2. Care necessary in the same stage (*a*) for the patient; (*b*) for the public."

It would be well if some similar question were always included.

Dr. Thomas F. Harrington, of Boston: In addition to the educational methods suggested by Dr. Hawes, the Boston School Department has inaugurated a plan of instruction which promises much.

The pupils in the normal school are given definite instruction relative to tuberculosis, its cause and prevention, and an outline of instruction has been presented to those pupils which has for its basis the presentation of the fundamentals underlying the whole anti-tuberculosis work.

One of the most effective means of impressing upon the teachers and pupils the importance of caring for health has been the establishment of "Health Day." On this day all the grades present programs dealing with tuberculosis and other diseases. The children present essays on the importance of fresh air, cleanliness, exercise and rest, food and drink, etc. The exercises in the schools on this day are arranged so that in each grade lessons are given "why" the windows are opened, exercise taken, positions in standing and in sitting corrected, etc.

In December, 1909, over 90,000 children were examined by the school nurses, teachers and medical inspectors, and over 5,000 were judged by the medical inspectors to be anemic, glandular, undersized or choreic. Special open-air rooms have been provided for this class of children, and opportunity is given for procuring, at a cost not exceeding two cents, a suitable lunch each day.

The School Committee has placed scales and measuring rods in each district, and the school nurses have been instructed to keep weekly records of the weight of each child. These children are not tuberculous children, but rather the predisposed.

For the purely tuberculous children, a special school has been maintained at Franklin Park. Since the opening of the school in 1908, 196 children, ranging in ages from five to sixteen years, have been admitted. Forty-three of these children have been returned to their regular grades cured, and many have been promoted into higher grades while attending this open-air school. Each "cured case" is followed up by the school nurse, and each is examined in the Burroughs Place clinic once a month.

In addition to these special classes, the School Committee has changed its rules and regulations so that each schoolroom, dressing-room and corridor is flushed twice during each session with air from outside the building. All the windows are thrown widely open. A fixed standard temperature of 67° F. has been established for the schoolrooms.

The investigation in Boston would seem to indicate that demonstrable tuberculosis is comparatively rare among school children. From 3 to 5%, however, of all school children can be classified as pre-tubercular. The open-air rooms established by the School Committee are for this latter class, many of which would gravitate into the tuberculous class unless saved. It seems far wiser in presenting preventive measures to teachers and pupils to avoid, as far as possible, emphasizing any particular disease, such as tuberculosis, and to make the lessons general so as to apply to general health.

Dr. W. W. Marvel, of Fall River: I would say that we in Fall River have used practically all the methods outlined in Dr. Hawes' paper. We have had exhibits and given lectures. The large exhibit was valuable in bringing the crusade before the whole people, and now we do more detail work with small groups. Our experiences with lectures have been rather disappointing, as we have found difficulty in getting audiences. We reached a number of people by addressing the various trades unions, and, to reach the largest number of the poor, we arranged several popular illustrated lectures, the audiences ranging from four to four hundred on Tuberculosis Sunday.

However, our most effective work has been with the traveling school exhibit. We realized that the subject should be presented in an interesting, instructive and simple way, so we covered practically the whole scheme of general hygiene in as nice and cheerful a manner as possible. The hearty co-operation of the superintendent of schools, Mr. Durfee, was secured, and he saw to it that the exhibit was placed in every school building. The corridors were used, and the exhibit remained a week in each place. The way the teachers took up the proposition to help their teaching of hygiene was surprising. There were assemblies of scholars addressed by physicians and prominent citizens, and special instruction by the teachers themselves. The children returned and told what they had learned, and in the higher grades essays and papers were prepared. I have brought along a few samples of this work and you will agree with me that the results certainly justify the work. What a child has taken the trouble to look up and write about is very apt to remain with him throughout life. This is from a child in the fifth grade:

"A careful person will never spit carelessly. Spitting causes consumption. A careful boy will never sneeze at the table; when he feels it coming on he should have his handkerchief ready. No one should exchange chewing gum, because he not only gets the gum, but he gets some of the saliva, too, and he also gets the germs, if there are any. He should never take a bite of anybody else's apples or other food."

Here are some more:

"Last week we had the tuberculosis exhibit at our school and it was very interesting. I think we should learn many lessons from it. From the charts I learned 'how to make your home, your school and your city the cleanest, most healthful and best in the United States.'

"We have a fresh-air room in my school, and I am in that room. In other rooms I have been sickly and had headaches, and made a large number of absent marks.

"But this year it is quite a change, the fresh air is

fine. I have not been absent this year for myself. Our teacher, Miss Leat, knows what is good for us. She has made a healthy girl out of me.

" 'The only consumptive to be afraid of is the careless consumptive. He coughs and spits anywhere and everywhere.'

" 'Take the doctor's advice and 'Don't sleep where there is no *Fresh Air*. Don't work where there is no *Fresh Air*. Sunlight and *Fresh Air* kill the germs.'

" It is dangerous to drink out of public fountains; if you ever want a drink, carry your own drinking cup or drinking glass with you. If you see any rubbish around your home, school or anywhere, do not wait for somebody else to pick it up; do it yourself. 'Never spit on the floors in the home, workshop, store or mill; the dust from dried sputum spreads disease.'

" I think it was very nice for the Fall River Tuberculosis Society to send around to the schools the tuberculosis exhibit. I learned a great many things from it that I never knew before. I hope others have learned something, too."

Those are all from the fifth grade. They are all learning the same thing. Other children have brought out their artistic instinct and cut pictures from papers and post cards. Here is a picture of a young baby [holding up a paper] who is going to combat the disease with dumb bells. Here is one from Grade Four [holding up paper]. This child is probably seven or eight years of age.

One pupil says:

" Mr. McCreery is telling all the rooms in our school about consumption. Every room from No. 1 to No. 18 is going into the hall to see the exhibit. It was sent by the Anti-Tuberculosis Society. This society is doing everything it can to prevent consumption. We learned about this society when we came into school last September. One day Miss Flanagan told us a story about a pretty little girl with golden hair who died of consumption. At Christmas time, when we brought money for our party, every boy and girl in the room gave a cent to help the consumptives. Now we are going to help this society and help ourselves. We must try to prevent the spread of consumption. First we are going to be clean all the time. Take a bath every night, wash and brush our teeth, and brush our hair. Then we are going to keep our yards clean, and sleep with our windows open. We will try to keep the flies off food, and never bite from anything, candy or apple, that belongs to another."

Here is another one, probably the child of a doctor:

" If you have consumption, do not pay any attention to the advertisements in the paper, but go to a doctor and you will be cured. Do not go too late. Go just as soon as you are not feeling well. If you cannot be cured at home, you can go to the tuberculosis home. Out there there are tents a few feet from the ground so that the person who is in bed will not find it too damp for him. Sleep from eight to ten hours. When you get up, do not be afraid to go out in the open air, because that will cure you, and then rest. Eat proper food; no pie or cake. Drink all the milk you desire to, and a piece of beef steak is good nourishing food."

Now another school has presented this [holding up a number of letters] in book form, and the children went at this scientifically. Those children have written directly from what they saw at the exhibit, but these other children, seven, eight and nine years of age, have gone down to the library and this is the result. They were investigators. They have drawn pictures of the tubercle bacillus. Our exhibit is almost absurd because it is so simple. I have brought along a few photographs of our exhibit. It did not cost over fifty dollars. It has a box that holds the slides and a strong standard and some steel rods on which are hung these placards.

DR. WALTER G. PHIPPEN, of Salem: We have used all of the various educational methods that have been described by Dr. Hawes with varying results. Of course the exhibit was the first one we used, and it served its purpose well. The press we have used very largely, and, in one way not spoken of here, a method used by the board of health, the so-called Health Question Box. Each edition of the paper had a column devoted to questions about tuberculosis or about health in general, and in the next edition of the paper these questions were answered by the physician. I think that helped considerably.

We have not used lectures very much because the greater part of our population we want to reach are Poles, Armenians and French Canadians who do not understand English.

I wish to reiterate what has already been said, that a trained social worker and a trained nurse are very essential. We have only recently been able to have both. We have now a trained hospital nurse. A great deal of attention is being given to keeping in touch with the children in families where tuberculosis has been known to have been previously, and in seeing that they are properly educated. We have a conference with the local board of health which has brought about very good results already, and we are trying to bring about many more.

There is one branch of educational methods which has not been spoken of this morning, and that is educating the people not to have an excessive fear of tuberculosis patients. That fact has recently been brought to my attention because a landlord has requested a tuberculosis patient whom we have had under our control for three years to move because the other tenants in the house have complained. I think there is a field for a great deal of work. It seems that a large number of patients who do not have tuberculosis definitely, but would be classed as susceptible, and whom the physician thinks needs to take regular treatment, the open-air, fresh-air treatment, do not like to do it. They say, " I have not tuberculosis. If I sleep at night in a tent, people will say I have tuberculosis." It is the fear of such a patient as that that we want to combat.

DR. L. M. PALMER, of South Framingham: The only help that I think I can bring to this discussion is to speak of the work that we are doing in Framingham. I think that the plan we have in our town, a town of some thirteen or fourteen thousand, will illustrate what can be done. We have one organization with a big name to it which includes a District Nurses' Association and a department for antituberculosis work. We have three departments of that society with a board of seven directors for each department, making twenty-one in all, and those twenty-one meet monthly and compare notes, and in this way the work of one department overlaps another and so we keep in touch with all. One person does practically the work of the three departments. She takes the place of a social worker and a nurse, which has been objected to here by one of the speakers as one and the same thing. She makes a daily visit to these cases of tuberculosis in the acute form, or has the nurse under her care do it, or in case the patient is not sick enough to see so often, at longer intervals. She also provides for daily care for the sick through the district nurse, a plan that works very well indeed.

Reference was made to the Dennison factory. I want to add my commendation of that work. It is a work that is bound to increase. The amount of good that one social worker who is also a nurse can do to a great manufacturing plant like that is excellent, especially if she is tactful. The operators like her and go to her for things

that they would not go to any one else for. She does a great deal of good. I think the growth of the industrial nurse is going to be very rapid in the next few years.

I want to emphasize what has also been spoken of before this morning, — the fear of the people of the tuberculosis cases. I think there is a danger about overeducating the public along this line. We make them afraid. I think this is a point that we must look out for. However, this is not, to my mind, the greatest trouble. My greatest trouble is to convince them that they have got tuberculosis. Up to the present time I do not know what to do with cases that say they have not got it, will not be looked after, will not give up the positions which they are holding. In the case of a table girl, have we the authority to subject this class of people to treatment, and can we put the law to them and restrain them? I am uncertain about it. I shall be glad of instructions.

Dr. A. T. Cabot: I will say in answer to Dr. Palmer's question that the State Board of Health has authority if they have a desire to exercise it.

Dr. Palmer: How will they do it?

Dr. A. T. Cabot: By the laws that they have.

Dr. E. St. J. Johnson, of New Bedford: Having listened with much interest to the various speakers, I would say, for my own part in the discussion, that the work accomplished by our own state and its various cities would count a great deal more, and be much less expensive, if certain problems entirely beyond local control could be thoroughly understood and taken up by the federal government. These problems and the education against tuberculosis naturally vary, as Dr. Hawes has said, in different places, and I mention those which are more prominent in a city like New Bedford, which, as most of you know, is largely made up of cotton mills run by foreign labor. In New Bedford a number of people are making a determined fight against this disease, which was exceedingly prevalent among the poorer classes when this crusade began in the state. This crusade has been and is at present being waged by the following organizations: First, the anti-tuberculosis society. Second, a local sanitarium, the Rockdale Hospital, which is soon to be moved to more commodious quarters. It takes all cases which cannot be treated at home. Third, the so-called chest clinic. This organization keeps track of ambulatory cases and improved cases returned to work. Fourth, the district nurses' staff, which reports any cases and brings cases to the clinic. There are eleven registered cases so far as we can trace them. By this means education is being placed, and we are striving to seek the best available methods of cure. Good results have been obtained, but we intend to have better ones in the future. The state is helping us a great deal, and methods of increasing such results may perhaps be considered under the following headings: First, instruction of immigrants before they start out. They should be made familiar with the conditions here, and what they must do to favor the conditions of health when they come into the country. The federal government has looked after Cubans in Cuba and Filipinos in the Philippines. Why cannot its representatives tell these people the truth about conditions here. Second, the registration of cases by doctors is very important. There should be a fine placed upon those who fail to report investigated cases. A fine for a non-registration of a case of tuberculosis is an important question. These cases cost the state, unless seen early, perhaps four dollars a week for life. Is this economy? Third, the local board of health. I hope some day the membership of this body may be made by state appointment and that it will have at least one well-educated, independent physician among its members. Fourth, extravagance. In our city all classes are given over to a most reckless, senseless and spendthrift use of money on things which are not essential to the best methods of health. Fifth, social service work in connection with our clinics, paid if possible, composed of enthusiastic workers, medical and social, to follow up the cases and to see that they are examined, and to constantly repeat doctrines of common-sense living, with assistance where necessary from the churches and charities to carry this out. Each patient should have at least one volunteer worker especially interested in his or her case, who holds the patient to the required standards by constantly repeating the principles of hygiene day after day, week after week, and year after year. I must say the available people in our city are painfully few, and that such work is handicapped by personal rivalry, politics, individual misunderstanding and race prejudices so common to human nature in all ages.

We have not made use in New Bedford of the maps, the school-nurses, the outdoor schools or the small exhibits. I hope we shall later. We are going to try.

Dr. E. O. Otis, of Boston: It seems evident from all that has been said here, and from the present stage of the tuberculosis campaign, that from this time on the educational propaganda must be largely carried on through the schools. In this state especially does this seem to be true, for we in the Boston Tuberculosis Association have found that there is no longer a demand for the traveling tuberculosis exhibition, and it has been retired. Coming as a delegate from the Boston Tuberculosis Association, I wish to refer to an interesting and unexpectedly disappointing experiment the Association has been making the past year, namely, that of a night camp. In an open space of thirty-five acres in the suburbs of the city, at Mattapan, a very comfortable night camp was erected with twelve bedrooms or separate sleeping apartments, open in front, somewhat after the plan of the "lean-to." This camp was within a five-cent fare from the city, and was intended for cured and arrested cases who had returned to their work in the city. Breakfast and dinner or an evening meal were furnished besides lodging, and for this a charge of $6.00 per week was made. We of the Association, as well as Dr. Hills, the superintendent of Rutland, thought there would be no difficulty in filling our twelve rooms with returned Rutland cases or other arrested cases who desired to continue the hygienic and open-air treatment which had been so effective in the cure. To our disappointment, however, we never have been able to fill our rooms, although we have advertised the camp extensively, particularly with all Boston patients discharged from Rutland. Whether they have grown tired of institution life or any suggestion of it, or for some other reason, the fact remains that up to the present time the experiment has been rather disappointing.

Something has been said here regarding the obligation laid upon the physician in the tuberculosis warfare and education of the public, and it has been intimated that he has not always fulfilled this obligation. Of course it goes without saying that it is incumbent upon the physician to do everything in his power towards the prevention of this great plague. I must confess, however, that I have much sympathy for the hard-worked and poorly paid general practitioner. It seems to me that either one of two things will have to take place in the future. Either have a free tuberculosis dispensary for the examination of suspected cases, whether able to pay or not, maintained by the state, municipality or town, and pay the attending physician a reasonable recompense; or else confine the attendance at such a dispensary strictly to those unable to pay for services, referring those able to pay something to the physician at his office. Tuberculosis work both in prevention and education is for the benefit of the whole community, and

the community should bear their share of the expense and not put an undue proportion of such work and expense upon the poor physician, who, as a rule, I believe is always ready to contribute his fair share of service for the public good. Even in tuberculosis dispensaries for the poor alone I believe the physician should receive some recompense — as is the case in the out-patient department of the Boston Consumptives' Hospital.

DR. J. J. MINOT, of Boston: I think the important thing in the future is the education of the child and the use of the nurse and the social worker, and I think that these schools are a great service in educating the public and in educating the children. I think that there are more tuberculous children in Boston than is generally thought. There has been no trouble in curing the ones at Franklin Park. If anybody wants to see the school, it is open all day from eight in the morning until four-thirty in the afternoon except Sundays, and visitors are welcome.

DR. HAWES: I have nothing further to say except that the summing up of the whole thing is the handling of the children in the future, and getting more and more nurses and social workers, and that when we get requests for information as to how best to spend a certain amount of money that has been given to the society, the question of paying a nurse and paying her well to handle the problem in conjunction with the physician should be carefully considered.

THE PERSONAL RELATION OF THE PHYSICIAN TO HIS PATIENTS.*

BY OLIVER H. HOWE, M.D., COHASSET, MASS.

IN these days of marvelous achievement in medicine and surgery, we can scarcely keep pace with the march of new knowledge. With myriads of new synthetic compounds, with the introduction of serotherapy, with the new applications of electricity and the daring advances of surgery, our heads are well-nigh bewildered with the great mass of new medical nomenclature. Attractive and valuable as are all these subjects, it is not to them that I would draw your attention to-day, but rather to another feature of our daily work, less novel, but perhaps more vital — the personal relation of the physician to the patient.

A venerable physician told me, many years ago, that the healing art consisted of medicine and the doctor. If we recollect some of our own illnesses, we shall realize the force of this remark. The tumbler of medicine had its place, and the spoonful was religiously taken, but we best remember the kindly presence of the doctor, the thoughtful inquiries, the reassuring manner and the cheering words, all coming like a gospel from the great realm of sunshine and vigor. Before he came, the atmosphere of our room had been as Hamlet described, "All sicklied o'er with the pale cast of thought." His presence had changed all this, for he had left with us a conviction of God's sound, sane world and that we belonged to it and would soon be resuming our part in it. He had left us something of himself, for he personated these sound, strong elements. We felt that we were leaning upon him, and that he was a power. We treasured his words and eagerly awaited his coming, for it was the one interesting event of the day. Later, as we were propped up on pillows, and caught sight of his gray ulster as he approached the house, our symptoms immediately abated.

The personal relation is more important with the physician than with any other individual in the community. He brings the child into the world and perchance breathes the breath of life into it from his own lungs. He watches its tender years through the perilous events of infant feeding and the alarming diseases of childhood, and is urgently sent for in case of accident. The knife in his steady hand is trusted by all, and his counsel is asked for the manner of education and kind of employment for the young man. In turn he is present at his wedding and later attends to the needs of his growing family. In many cases he knows the whole life of the individual; watching him day by day through a lingering illness and easing his pillow in his last moments. Often he consoles the bereaved family more successfully than the clergyman. Perchance in time he may attend five or six generations of the same family. Such is the life we know, and exacting and laborious as it is, I doubt if any of us would exchange it for any other. Other workers are paid in coin of gold and silver. We receive, in addition, the tribute we most prize, in the coin of friendship and of respect and in the consciousness of doing good. Beyond this, it is in the province of most men of business to urge their wares or their services upon those who do not desire them; to sell to the reluctant customer; to obtain a hearing where such is not desired. The physician is relieved of these insinuating and distasteful methods. He goes only where his presence is welcome, and many times the front door is flung wide open to receive him, with the salutation, "O Doctor, I am so glad you have come!" These facts, and others which we well know, make it plain that our profession is unique in its opportunities, its privileges and its rewards.

The increasing concentration of population in cities and the strong tendency to specialism threaten to leave the general practitioner in the minority. No member of the profession, however, can reap so great a reward in personal satisfaction as the general practitioner. His bonds of friendship and sympathy are strongly developed and the family doctor has a vital and intimate part in the life of the community.

It should be our aim to fulfill the responsibilities of our work and the expectations of our patients as well as in us lies, and I propose to spend a few moments in discussing what seem to me to be the essential elements of the matter and how we may further increase our usefulness to our patients through the personal relation. In so doing, I find that I have drawn my material largely from a study of my own deficiencies and I therefore disclaim any intention to dictate to any one else, and I state that any

* President's Address, Norfolk South District Medical Society, May 5, 1910.

duties I may suggest, I am ready to take to myself in equal degree.

The most obvious need of our professional life, as it seems to me, is that we more thoroughly individualize our patients. Classification, as we see it in hospitals and in medical literature, tends to merge the individual in the mass. We speak of so many cases of pneumonia, and then detail our pet treatment, which has been so successful in them all. The patients, however, are not alike. They do not look alike or react alike, either to the disease or to our remedies. We need, to a greater degree, to think out each person's environment and resources; to weigh each person's antecedents and powers of resistance, and then treat him according to his individual needs and practical resources. The failure to individualize has been intensified by the changed meaning of the word "case." To my mind, a case is properly a record of a sickness, filed for reference or tabulation. To speak of making a visit to-day, I think we can more properly say that we have visited a sick person or a patient. To call him a case seems to me a barbarism and a term which may prevent us from considering him in his true relation. I know the dictionary sanctions the current misuse of the word, but believe the restricted use I have suggested is truer to our best intent. Specialism is responsible for much of the failure to individualize. The specialist sees the patient usually in his office, and has little or no opportunity to know his surroundings or his real life. We general practitioners know whom we treat, and the family tendencies and traditions as well. Let us profit by our knowledge and adapt our treatment like a well-fitting tailor-made garment, cut to his measurement.

To say that the doctor should treat his patients with kindness seems like a truism, and yet the conditions of our professional life show that the problem is by no means a simple one. The patient is suffering from bodily ills, and the mind partakes of the disorder. Let us suppose that we have before us a hard-headed man of business, keen and quick in judgment, accustomed to deal promptly with new conditions of his business, and inclined to be optimistic in general. Let him lie in bed a few days and suffer more or less pain and he becomes a different creature. He has been accustomed in his business to have matters respond promptly to his touch, like the levers of his automobile, and now to deal with an attack of rheumatism or pleurisy, either of which requires time, is a new experience for him. Two or three hours of wakefulness at night become peopled with phantoms of the most terrible nature. His nerves become screwed up to a frightful tension, and all his surroundings are distorted by a mischievous mirage. He loses his patience, his judgment and his ordinary good cheer. To deal firmly, kindly and helpfully with such a patient is no ordinary task. Too direct and matter-of-fact a course will only increase his concentration on his symptoms and will lead him to remark that the doctor has no sympathy. Too sympathetic a manner will make a baby of him. He must, of course, be made to feel that the doctor takes a personal interest in his condition and that he is exerting himself to the utmost for his welfare. With this must be mingled much of the helpfulness of the doctor's personality. Some diversion must be added, some amusing story to break the spell of his over-wrought nerves. The doctor must bring something from the outside world, and must show by his manner a firm confidence in his recovery. To carry out this personal influence successfully, the doctor must imagine himself in the situation of the patient and get to see things as much as possible from his point of view. In this way he will be prepared to meet the misgivings and weaknesses of the patient in advance of their manifestation, and being in the lead is always a good thing in the practice of medicine. We thus see that the kindness of the physician is a mixture of ready observation, fore-thought, sympathy, firmness and wholesome personality with tact. He who can best mingle these ingredients will have the strongest and best personal influence with his patients.

The proper treatment of the sick has diversity enough, but the personal influence we exert varies immensely. With some we agree and sympathize. With others we puncture the bubbles of their imaginary ills and dispute their pet forebodings. Some we scold in a playful manner, and with others we laugh and tell a story. A keen sense of the humor of life is a valuable asset for the physician. It must be used judiciously, however, and with circumspection. It is generally wiser not to descend quite to the point of boon-companionship with our patients, for if we do we may later find that we have suffered a lapse in our authority.

All of us have days when something apparently goes wrong with the planetary system. We have been delayed in an aggravating manner; some patient has proved refractory, or our plans for a leisure evening have miscarried. We ought to be particularly careful not to allow any of these matters to disturb our outward serenity, for the doctor who carries pessimism or indifference or his own troubles into the sick room, is poisoning the atmosphere of that apartment with malignant vapors, which the afflicted one must breathe for many hours.

We often find at the close of a busy day that the drain upon our sympathies and the effort of adapting ourselves to all sorts of people have well nigh exhausted our good nature, and we have only the dregs of our personality to offer our families at home. This condition, if it become in any sense a habit, is most deplorable, and we must not allow it. What could be worse than to give all our good qualities to strangers and treat those we love best with unkindness!

Probably nothing contributes more to frank and open relations between doctor and patient than the belief that the physician will keep inviolate all statements made to him. The doctor who will retail any of the weaknesses and peculiarities of other patients may be thought very entertaining and amusing, but his listeners will not, in turn, confide to him their secrets. Again, in re-

lation to patients under treatment, they are to pay the doctor for the care and thought devoted to diagnosis of their ailments and, therefore, have a property right to the same. The patients may, if they so desire, impart the information to others. They are the proper ones to impart it — not the doctor. It may be said that the doctor need retain only suspicious and unpleasant information. This is a fallacy, for should he follow this rule, his occasional silence would bear a ready interpretation. No clearer statement of a physician's duty in this regard can be found than that contained in the celebrated oath of Hippocrates, as follows: "Whatever in connection with my professional practice, or not in connection with it, I see or hear in the life of men which ought not to be spoken of abroad, I will not divulge, as reckoning that all such ought to be kept secret. With purity and holiness will I pass my life and practise my art." Hippocrates lived four hundred years before Christ, but who can voice a purer or more elevated sentiment to-day?

That the personal relation of the physician falls short of what it should be is evidenced by the substitutes which the public adopt from time to time. Instead of considering each and every one of these as a willful, deliberate and wicked wandering of human nature from the truth, we should try to learn the underlying reason if there is one.

I judge that before the introduction of homeopathy, there was a dogmatic and uncompromising insistence on large and nauseous doses and that some of the profession may have taken a savage delight in inflicting them upon suffering humanity. Much as we disapprove of the principles of homeopathy, we find it, in one sense, a revolt against the domineering spirit — a very bad spirit for a beneficent profession to manifest. With our present pharmaceutical resources, the potent alkaloids and other new additions and improvements, we can meet the tastes and wishes of our patients in such a manner as we would like if we were the sick ones.

The patent medicine evil also may have a lesson for us. It may be that many of us have dealt and prescribed our medicines in too mechanical and matter-of-fact a way, without the comforting explanation to the patient which will link it to his symptoms and serve to fasten his faith upon it. It is, therefore, possible that the patient resorts to the patent medicine because he finds the literature abundant and optimistic and because his doctor fails to give him the information which his curiosity demands.

So with the present cult of osteopathy, I believe it exists because of a genuine disregard by many of the profession of the valuable aids of massage, passive exercises and gymnastics, and perhaps of well-chosen external applications in disease. The patient cured by the osteopath is apt to exclaim, "Why, my family physician treated me for weeks and weeks and never gave me any external treatment!" I believe some of us (myself included) are deplorably ignorant about many kinds of treatment which are perfectly legitimate for us to use, and beneficial to the patient. Let the profession as a whole become skilled in the use of massage, exercises, vibration, electricity and the like, using them personally and after discriminating diagnosis, and I believe osteopathy will disappear.

The Emmanuel Movement and Christian Science attempt to furnish in an abnormal sort of way a sustaining sympathy and encouragement which the profession ought to provide. I believe they flourish because of the declining power of the personal qualities of the physician. The profession has in some ways become indifferent, unsympathetic and perhaps commercial, as regarded by the patient, whose spirit languishes and yearns for some special influence which the doctor does not supply.

Now these various heresies — patent medicines, osteopathy, the Emmanuel Movement and Christian Science — are all absurd because they omit the intelligent, skillful, warm-hearted and sympathetic personality of the physician. Our feelings are perhaps impelled to make a crusade against each of them, putting in such vigorous arguments as to completely demolish them once for all. I do not believe such a method would succeed and, in my opinion, a far better way is to prove to the world by the daily work of the profession that we are providing the best and most helpful assistance to the sick. Such proof, however, implies an uplift in the medical profession — a further awakening to our responsibilities and to the personal power which we possess. It is not enough that our diagnosis be faultlessly correct, our treatment well chosen and firmly carried out, all these may be perfect and yet not impress the patient. There must be the essential link of personal influence, which must carry to the heart of the patient, conviction that he is under sympathetic and effective treatment. This is a sheet-anchor which he will not cast off.

Curiously, doctors are most praised for little kindnesses which lie outside the ordinary range of their professional duty. Such are the unexpected friendly inquiry, the personal letter, the little delicacy secured for the invalid's table — the thousand and one little acts that imply thoughtfulness and continued interest. Dr. Charles C. Tower, of South Weymouth, whose memory is revered by all who know him, went twice a day for several years, to lift a helpless old man from bed to chair and back again, because the doctor could lift him a little more gently than any one else. Such acts as this, performed out of kindness and often without compensation, endear the physician to the community in a manner experienced by no one else. This tendency in public feeling is not always in line with our preferences, for we often think they ought to more definitely admire our skill and the prompt action by which we turned the tide of illness. But no; the public cannot appreciate diagnosis or erudition. They have their own ways of looking at things, and it is really the overflowing of the cup that attracts attention. If we would succeed as we ought, we must pay due regard to the patient's standpoint and look at things ourselves from his point of view.

Perhaps this is the key to the whole matter. We must see both sides and must never cast away with scorn the true feelings of any patient, however humble. It is a mutual relation and, like all mutual relations, it is one of delicacy. The physician is in duty bound to treat it delicately and with thoughtful regard, being more solicitous to cultivate the fine flower of friendship than to secure distinction or income.

Many times we are disappointed and fail of praise or credit when we think we most deserve it. Be this as it may, let us never lose our confidence in human nature, and let us never become pessimistic, even when we turn the barren pages of our ledgers. A patient can injure the doctor by nonpayment of his bill, or otherwise, but let it never be said that any patient or collection of patients can transform the doctor into a pessimist. I am not one of those who habitually bewail the trials and injustices heaped upon us. They are hard to bear, at times, I admit, but, personally, I have received credit in countless instances where I felt I had not deserved it. Setting these accounts over against each other. I have always felt, in my own case, that they balanced fully as well as I deserved, and I believe the doctor should be always and everywhere an optimist.

The broad knowledge of the whole community possessed by the physician fits him in a marked degree for various local public services, such as those relating to health, charity and education, by which he can help and safeguard the public. Into such work he should bring the same spirit of service that animates his profession.

The more we consider it, the more we wonder at the extent and importance of the personal relation of the physician. It is indeed the most important personal relation in the world, outside the family. To enter into the life and feelings of all classes in the community, we need broad foundations of character and broad sympathy with very varied interests. To adequately fulfill our duty, we need a broadening and enlargement of the whole nature. Thus and thus only can we lead the public back to right ways of thinking and redeem the medical profession from any weaknesses or misconceptions which now exist.

THE NECESSITY OF THE GENERAL PRACTICE OF MEDICINE AS A PRELIMINARY TRAINING FOR THOSE ENGAGED IN SPECIAL WORK.

BY CAROLUS M. COBB, M.D., BOSTON.

The belief that the practice of general medicine was necessary as a preliminary to special work was formerly held not only by the general practitioners, but by the specialists themselves. The higher emoluments which are supposed to come to those who do special work has attracted a constantly increasing number of young men without experience in general medicine, until at the present time an overwhelming majority of specialists have had no experience in the actual practice of medicine. Furthermore, many of them have received their degrees from schools in which the requirements for graduation are barely sufficient for the graduate to pass the State Board of Registration. These degrees are obtained for the express purpose of enabling the graduate to enter special work after a brief course in a special hospital. The special hospitals lend their aid to this condition for the very evident reason that the recent graduate has the necessary time to serve as interne, clinical clerk, assistant and through all of the slow process which finally leads to a full surgeonship. The tendency of all this is to widen the breach between special work and general medicine, with a loss to both, but with by far the heavier loss to specialism. We see, very largely, what we are taught to see, and the specialist has a tendency to forget that the small area of the body upon which he spends his time is but a part of a complex physiological whole which is influenced by general conditions.

The shorter the time one has practiced medicine, the more easily one sees nothing but what is in his special field. If specialism is to continue to be a useful part of medicine, it is high time that the general practitioner demands that the specialist is well-trained and that he has also practiced general medicine. It is not to be expected that every good doctor will make a good specialist, but it should be remembered that a good specialist cannot be made out of anything but a good doctor. If specialism is to hold the respect of the profession, a change must be made in this direction because the daily occurrence of cases like the following can have but one result.

Case I. Mrs. I., aged thirty, consulted me for epiphora and gave the following history. She had first noticed it about three years before and had gone to a special hospital for treatment. The surgeon evidently did not find much the matter, as the treatment recommended was simply the wearing of weak convex lenses for near work. She next consulted a specialist of some note, who informed her that the tear ducts were closed and proceded to probe them; as she did not obtain relief from this treatment, she then consulted a noted specialist, who in turn fitted her with glasses, + 2, for near work. The epiphora continued, and in about a year she consulted him again. He again prescribed glasses for near work, + 2.50 this time. She then came to me, and I could not find anything wrong with the eyes, and she repeatedly asserted that she had not received any relief from the various lenses which had been prescribed. I asked if she had any stomach trouble, and she said she had, but she did not look badly nourished and from her description of her trouble I gained the impression that she was extremely nervous. I then asked her if there was anything troubling her, and her eyes filled with tears and she replied that she was unhappily situated. Here was the explanation of her epiphora. I told her it would do her no good to go from one to another and have her glasses changed, as

glasses would not prevent her from weeping over what she considered an unhappy situation.

CASE II. Mrs. —, aged forty-five, living in the northern part of the state, consulted me about her throat and gave the following history. She had suffered for some years with attacks of pharyngitis and had consulted a specialist, who advised the removal of the tonsils, to which she consented, and after the operation she went to Connecticut for several months and while there she was free from sore throat. She returned in the fall and soon suffered again from her old malady. She again consulted the specialist, who informed her that there were still islands of tonsillar tissue scattered over the back of the pharynx and advised her to take ether again and have them all removed. She demurred at this and later consulted me. When I saw her she still had the islands of tonsillar tissue, but the throat also had the appearance which would lead one to think the patient might have idiosyncrasies in regard to food. With this idea in mind I questioned her in regard to what particular article of diet poisoned her, and she told me fruit, and particularly apples. The explanation of her freedom from trouble while in Connecticut was that she abstained from fruit, but when she came home again she told me her mother had a large quantity of apples and grapes, of which she ate freely and the trouble with her throat was soon as bad as ever. I could only tell her that if she ate fruit she would have pharyngitis whether she had the throat operated upon or not. The specialist whom she consulted is an able man, but he was trying to remove by operation a constitutional condition, which not only cannot be done, but it reflects upon specialism to attempt it.

CASE III. Miss V., aged thirty-six, consulted me about obstructed nasal respiration from which she suffered and for which she had had her nose burned, sawed and cut by specialists all the way from Denver to Boston. She was thin, nervous and suffered from constipation. There was no nasal obstruction, but she was suffering from intestinal absorption and the nasal cilia were matted together by a glue-like secretion which is often present in the nose under these conditions. A prescription for the relief of the constipation and careful directions in regard to diet led to a marked improvement. She feels that a large part of the surgical work which has been done on her nose has been unnecessary, and I am inclined to agree with her. I do not know of any class of operations which give so much relief as do necessary operations upon the nose and throat, but when a patient is subjected to one nasal operation after another, and by different men, to cure a condition which is the result of intestinal absorption, one can hardly be blamed for wishing that the specialists had a little less special training and knew a little more general medicine.

Paget long ago made the remark that "no disease can be properly understood unless it be considered in its whole pathology," and the same condition exists to-day. Diseased conditions have not changed, and manual dexterity and facility in fitting glasses should not entitle one to the name of specialist. The only motive one should have for practicing medicine is that he is able to relieve suffering humanity, and a specialist should be doubly trained else he will fall far short of what the public has a right to expect.

Clinical Department.

TIBIALE EXTERNUM AND FRACTURE OF SESAMOID. REPORT OF CASES.

BY CHARLES F. PAINTER, M.D., BOSTON.

(From the Orthopedic Clinic of the Carney Hospital.)

CASE I. Mr. X. entered the Carney Hospital in May, 1910, complaining of pain in the inner border of the right foot, especially when walking. He states that about three months before this time he was running upstairs rapidly, two or three steps at a time, when he felt a sudden, acute pain in this part of the foot and he was obliged to stop running immediately. Presently the foot commenced to swell somewhat in this region and became very tender to touch in a small area about the size of a fifty-cent piece over the mid-portion of the inner border of the scaphoid. He kept off it as much as he could and applied a bandage around the foot in this situation. This helped, but pain continued to some extent, and whenever he made any considerable effort in walking the discomfort at once became aggravated, the swelling more pronounced and he was obliged to yield to it. He had never experienced anything like it before; there was no ecchymosis about the foot at that time. During the two or three weeks preceding his coming to the hospital there has been no improvement in the condition.

On physical examination, the right foot was slightly swollen over the region of the scaphoid and internal cuneiform, and over this swollen area there was acute tenderness upon pressure. There was no redness or increase in the surface temperature. The motions of the foot at the ankle and the mediotarsal joint were to all intents and purposes normal. He walked with a slight limp.

Protection of the foot by plaster strapping did not quiet the trouble down. An x-ray revealed a shadow that appeared very much as though a portion of the scaphoid had been pulled off. On examination at this time there seemed to be abnormal motion in the region where the tenderness was located and where the chipped-off piece seemed to show in the skiagram.

An operation was advised, and was performed ten days after he was first seen (May, 1910). On cutting down over the side of the scaphoid and exposing the insertion of the tendon of the posterior tibial it was found that there was a loose piece of bone about the size of a Lima bean, which seemed to have a false joint between it and the body of the scaphoid. The separation between the two bones was clean cut and not as though there had been a fracture. The loose fragment was so completely enclosed in the end of the posterior tibial tendon that it had to be carefully dissected out from this attachment. The expansions of this tendon to the lateral aspects of the scaphoid and internal cuneiform were not disturbed. A strong silk ligature was quilted through the distal end of the tendon of the posterior tibial and forced through a hole drilled in the scaphoid.

This was done to insure a firmer connection between the scaphoid and the tendon of the muscle.

The foot was then put up in plaster of Paris in an inverted position, after the wound had been closed, and a dry dressing applied.

In looking up the anomalies of the bones of the tarsus, I found that Dr. Thomas Dwight has described an anomalous bone in this situation which has been called the tibiale externum. This is figured in his book on the "Variations of the Bones of the Hands and Feet," Plates XXV and XXVIII, Figs. 61 and 62. I quote from his description (pp. 18–19):

"The tibiale externum is commonly known as the sesamoid in the tendon of the tibialis posticus, but it is a true part of the skeleton, being found in many mammals and being cartilaginous in the second month of the embryo. I have seen it as a separate cartilage at birth. Fig. 62 shows it in a child of two years. In about 10% this is a separate bone, generally closely connected with the tuberosity of the scaphoid by fibro-cartilage or fibrous tissue. It may play on it with a true joint, but more often the articular cartilage, even when present, shows signs of degeneration, and the two apposed surfaces tend to interlock. It is more or less involved in the tendon of the posterior tibial. It sometimes is quite free, having no close connection with the scaphoid, but, as Pfitzner has shown, it is never inclosed in the tendon. Its relation to the tuberosity of the scaphoid is uncertain, whether it persists as a distinct element or is consolidated with the latter. It may be placed directly internal to the tuberosity, but more often it is somewhat behind it, and sometimes so much so that it seems to form a link between the tuberosity of the scaphoid and the front of the sustentaculum, beneath and internal to the head of the astragalus. When fused it may stand straight out as a projection from the scaphoid, or it may bend backwards as a well-defined hook, or it may be so completely fused that its presence is inferred only by the size of the prominence. If it pleases any one to say that it is simply a very large tuberosity, there is no way of convincing him, nor does it practically matter. Pfitzner has once seen it subdivided, and in two or three other cases an imperfect division was indicated by furrows. The tendency of an independent tibiale externum is to be symmetrical. Thus Pfitzner found it 26 times on both sides and only 17 times on one side. He found it nearly twice as often in women as in men. As to size, the largest seen by Pfitzner had a chief diameter of 19 mm. He found but five under 5 mm., showing that very minute forms are rare. It is evident that this may be mistaken for a fracture."

In this case there was no evidence of a similar condition on the other side, and the relation of the bony fragment to the expansion of the tendon was a most intimate one, thus differing from the condition as Dwight has described it.

The result, from a surgical point of view, has been quite satisfactory, even at this short time since the operation.

A knowledge of the occurrence of this anomaly may be of service in helping to arrive at a proper diagnosis, for the symptoms may be so acute as to suggest even an inflammatory process in the tarsus. Prolonged fixation is not likely to permanently relieve a person from the occurrence of these symptoms when once the bone has been started from its moorings, and surgical interference seems to offer the best hope of relief.

Another seemingly anomalous condition in the foot has been called to my attention recently, or if not anomalous, still sufficiently unusual to merit a brief description.

Case II. Professor Dwight calls attention in his book (p. 22), to which reference has above been made, to subdivision of the internal sesamoid of the great toe. The case here reported was diagnosed, after the x-ray examination, as being a fracture of both the internal and external sesamoids of the right great toe. In the light of what Professor Dwight and Stieda, quoted by Dwight, have said, it may perfectly well be that the condition presented by my patient was not a true fracture, but an anomaly to which attention had never been called until the occurrence of the injury referred to below.

In August, 1909, Mr. D., a man sixty-six years of age, was summering on the Maine coast, and when going over the rocks one day to reach his boat he felt a sudden sharp pain beneath the ball of the right great toe. This pain was at that time very severe and had continued to be so whenever he stepped on that part of the foot, though there was no pain when weight was not being borne. He consulted me about six weeks after the accident, at which time there was no physical evidence of anything wrong with the foot except his lameness and tenderness upon pressure beneath the ball of the great toe. An x-ray showed a separation of both external and internal sesamoids into two portions, the division being a transverse one. There was no sign of callus formation. Both fragments were of approximately the same size.

Protection of the foot from pressure, at first in a plaster cast and then by a felt and leather support, fashioned to keep the ball of the great toe from resting upon the floor, eventually afforded relief from the discomfort of weight bearing and walking. The x-ray shows the condition very well. There is no fracture or division of the same bones on the other foot.

I quote from Professor Dwight's book (p. 22): "Subdivision of the internal sesamoid of the great toe is not so very uncommon, the division being by a cross line into a larger proximal and a smaller distal part. I have seen this several times both in the bones and in x-rays, and have seen once the external divided in the same manner with the suspicion of a longitudinal division of the larger piece. Stieda[1] found two sesamoid bones on the plantar aspect of the interphalangeal joint of the great toe, and at the same time a subdivided sesamoid at the metacarpophalangeal joint. The man had suffered from a previous injury to the ball of the foot. He saw twice a tibial sesamoid of the fourth toe in the x-ray."

[1] Beiträge zur klinische Chirurgie, 1904.

Though this condition does not apparently occur very often, recognition of its existence might be of importance, especially in prognosis. Sometimes bursal inflammations occur in this region and should be differentiated from this anomaly.

TWO CASES OF TRANSVERSE SUBPERIOSTEAL FRACTURE OF THE LOWER END OF THE RADIUS IN CHILDREN.

BY WM. PEARCE COUES, M.D., BOSTON.

THE importance of the recognition of these obscure fractures in children is receiving increased attention. From clinical examination, without radiographs, the diagnosis of these cases would have been impossible.

CASE I. M. P., a girl of nine years, was seen at the Surgical Clinic, Boston Dispensary, April 11, 1910. The history was as follows:

About ten days ago the child fell down hurting the left wrist. Some disability and pain followed, but it was not marked. Examination showed very slight swelling of the wrist. There was no ecchymosis. Flexion and extension of the fingers was perfect. The landmarks of the wrist were in normal relation. There was slight pain on pressure on the lower end of the radius; no crepitus or abnormal mobility was found.

The radiographs showed well the lifting of the periosteum in the lateral view and the slight bulging on either side of the radius in the antero-posterior view.

The crack running transversely across the radius about 1½ inches above the styloid was clearly discernible.

CASE II. T. S., eleven years of age, was seen at the Surgical Clinic, Boston Dispensary, May 16, 1910. The history was as follows:

Three days ago the child hurt her left arm in falling. Examination showed considerable tenderness over the lower third of the radius. There was slight swelling of the wrist; rotation of the forearm was painful. Flexion and extension of the fingers was perfect. There was no ecchymosis; no crepitus or abnormal mobility was present.

The radiographs showed well in the anterior-posterior view the same bulging on either side of the radius as in Case I. In the lateral view the irregularity to the ulnar side of the radius was plainly seen. The distance of the fracture from the end of the styloid process of the radius was almost exactly one inch. The transverse crack extending across the radius to the bulging periosteum on either side was slightly more marked than in Case I.

Treatment by fixation with posterior splint alone gave perfect results in both cases.

Medical Progress.

REPORT OF PROGRESS IN OTOLOGY.

BY HARRIS PEYTON MOSHER, M.D., BOSTON.

IN reviewing the otological literature of the last twelve months, the reader finds that labyrinthine diseases and surgery occupy the greatest space. The same is true of the literature of the previous year. Operative surgery, however, does not occupy the minds of all the writers. It is pleasant to notice that a few men have gone back to the basal physiological problems connected with otology; that is, that tremendously difficult subject of the physiology of hearing has been bravely attacked again by Shambaugh, and Walker has had the courage to make use of the ductus indolymphaticus in expounding a new theory of tinnitus and vertigo. An interesting and important article by A. A. Gray was published in the *Laryngoscope* on "An Investigation on the Anatomical Structure and Relationships of the Labyrinth in the Reptile, the Bird and the Mammal."[1] Besides this stimulating work, articles which show progress have appeared in connection with the x-ray examination of the mastoid for pre-operative determination of the cellular consistency of the mastoid process and the position of the lateral sinus. Beck has published an elaborate article on mastoid surgery. This is very complete and extremely useful to the operator on account of the numerous and illustrative drawings.

The use of cocaine for producing anesthesia for middle-ear operating, and for even such extensive work as mastoid operation itself, has been advocated in at least two articles. The presence of Neuman in this country, Neuman being the man who received a prize for his work in connection with cocaine anesthesia about the ear, also has stimulated interest in this subject. Neuman's classes in the various cities of the United States have stimulated interest in labyrinthine diagnosis and surgery. The use of vaccine therapy in connection with diseases of the middle ear is not new in the last twelve months. Considerable work had been done along this line in the last few years, but the general consensus of opinion seems to be that the vaccines were of but limited use. A paper, however, was read by Dr. E. W. Nagle, by invitation, of the American Rhinological, Otological and Laryngological Association, in Washington, which brought the subject up again and presented it in a new and more favorable light. This observer, working in connection with Dr. F. C. Cobb, of Boston, had extremely favorable results in curing chronic middle-ear suppuration by the use of otogenous vaccines. It became apparent in the brisk discussion which followed the reading of this paper that the writer's good results to date, differing as they do from the results of previous observers, were due to improved technic in preparing the vaccines. At this same meeting in Washington there was a symposium on the deaf child. This symposium was especially complete and brought this important subject up to date in all its bearings. The greater part of the symposium was given over to papers by professional educators of the partially and completely deaf child. The complicated subject of training the deaf child and the best methods of bringing this about were clearly set forth. Otologists furnished a certain amount of material in the symposium. This, though im-

[1] Laryngoscope, vol. xix, p. 161, March, 1909.

portant, was along the old and more familiar lines. The printed symposium furnishes a very valuable mass of material to which the otologist and general physician can refer for guidance in these difficult cases.

Turning from these more or less theoretical subjects, and coming to one of the very last articles published, the reviewer finds one which deals with a very practical and old subject, namely, the Eustachian tube. In the July number of the *Laryngoscope*, Yankauer, of New York, has an exhaustive article styled the "Isthmus of the Eustachian Tube." In this he goes over old ground and then strikes off in directions which are rather new. The article is clearly and modestly written. The conclusions given by the writer are drawn after a sufficient length of time so that they are not only convincing, but most stimulating.

In noting the progress of otology for the last year, it is necessary to record revised editions of certain standard textbooks. The English translation of Politzer's "Atlas" has appeared in the seventh edition. The textbook of Dench has appeared in the fourth edition. Both books are brought up to date by revising the chapters on labyrinthine diseases and surgery. In addition to these two large and notable books, a very short but valuable textbook has been issued by Yearsley. A small handbook by Lake is to be reckoned among the books of the last twelve months. The important clinical work done by Lake on the labyrinth appears in this clearly summarized.

At the Eighth International Congress at Budapest a committee appointed to consider the subject of hearing tests reported a universal formula for recording tests of hearing. This uniform formula supplies a need felt for many years. The formula can be found in the July *Laryngoscope* for 1910. The abbreviations of each test are the initial letters of the corresponding Latin name. This makes a test so recorded of international use. The pitch, however, is always given according to the German musical method. English-speaking aurists, therefore, who care to be scientifically accurate, and who, therefore, adopt this formula, will have to change their testing forks somewhat, or, what would be better still, to adopt the standard German forks. From the American standpoint it will surely be considered a noteworthy happening, if not exactly a sign of progress, that it was decided at Budapest to hold the next International Congress of Otology in Boston. This meeting will come in 1912. Dr. Clarence J. Blake, of Boston, is the president. Boston, and perhaps some of the other American cities, thus having had due notice of the coming meeting, will take advantage of the next two years to brush up, if need be, and to get in trim for the distinguished visitors who are to attend this meeting.

In reviewing the literature of otology for the last twelve months, the reader finds that labyrinthine and cerebral surgery occupy a large place. The results of the investigations of Baranay are being applied in the clinic, and articles explaining and simplifying his observations are numerous. American otologists are under obligations to Goldstein, Kerrison and Chamberlain for work in this line. Goldstein has translated the latest articles of Baranay, and Kerrison and Chamberlain have expounded and simplified the work of Baranay, Alexander and Neuman. The reviewer has used the American articles freely and wishes to express his obligations and his thanks to the three men mentioned above.

Otogenic Meningitis.

Dr. Mygind[2] says that his experience does not support the supposition that otogenic meningitis is the result of pus retention in the middle ear, but rather that the nature of the suppuration and the anatomic relations of the petrous portion of the temporal bone and the mastoid process play the most important part in the pathogenesis. The impression is, however, that the middle-ear suppuration now and then spreads explosively to all parts of the cranial cavity simultaneously, causing two or more intracranial complications. There is but one trustworthy objective sign, in his opinion, of this form of meningitis, namely, turbidity of the cerebrospinal fluid, caused by overproduction of round cells. He lays stress on this because otitis media can cause the subjective signs of meningitis, and also the objective signs, like neck rigidity and Kernig's sign, without producing diffuse purulent leptomeningitis. On the other hand, a few cases are reported in the literature of abscess of the brain and sigmoid sinus phlebitis, with turbidity of the cerebrospinal fluid, without the autopsy showing evidence of actual meningitis. These he is inclined to think are cases in which the patient has been cured of the disease before death from another cause.

Typical otogenic cerebral abscess differs from otitic meningitis in having a distinct prodromal stage, slower development of symptoms, more frequent focal symptoms and produces slow cerebration and slow pulse. All subjective and objective signs, however, may mislead excepting turbidity of cerebrospinal fluid. Clear cerebrospinal fluid does not absolutely exclude meningitis, as it always takes some time for the fluid to become opalescent. Beside lumbar puncture, there are two other diagnostic methods of value, namely, examination of the hearing and of the static part of the labyrinth by injection of cold water. If the labyrinth is destroyed, no nystagmus is produced, and this points to meningitis caused by destruction of the labyrinth. His experience of the operative treatment is limited to eighteen cases, in all of which the diagnosis was confirmed by lumbar puncture. Three patients recovered entirely, which he thinks is an encouraging result, though he admits the element of chance as having possibly a hand in the success of these cases.

STUDIES CONCERNING THE SURGICAL TREATMENT OF OTITIC MENINGITIS.

Alexander[3] states that meningitis studied in the dead house is hopeless and has led to but little if any advance in the knowledge of the disease. Studied clinically, however, he thinks the subject is not wholly unfavorable. In his paper, which is for the most part a clinical one, he discusses the usual forms of meningitis, that is, serous, purulent and tubercular meningitis. The first two kinds may be circumscribed or general. In connection with serous meningitis there is usually a superficial inflammation of the brain substance. Among the forms of circumscribed meningitis dwelt upon by the writer is circumscribed meningo-encephalitis occurring in connection with diseases of the labyrinth and thrombosis of the lateral sinus.

The writer makes the following classification of meningitis as it occurs in connection with diseases of the ear:

(1) Meningitis with uncomplicated, acute, purulent, middle-ear inflammation.

(2) Meningitis with uncomplicated, chronic, purulent, middle-ear inflammation.

(3) Meningitis with otitic cerebral abscess.

(4) Meningitis with otitic thrombophlebitis and extradural abscess.

(5) Meningitis with labyrinthine suppuration.

In each of these groups three different types of meningitis are found:

(1) Such types as retain an anatomically visible connection with the region of the ear.

(2) Such types as do not show any connection with the ear.

(3) Such types as are due to tubercular forms of meningitis.

SEROUS MENINGITIS.

From the observations made by Alexander on serous meningitis, the following are selected: Serous meningitis as a preliminary stage of diffuse purulent meningitis is more frequent than is supposed. In such cases, if lumbar puncture is made early enough, the cerebrospinal fluid is clear and it is evacuated under pressure. On standing twenty-four hours a fine coagulum appears. Later in the course of the disease the fluid becomes infected and cloudy. Serous meningitis is usually accompanied by a superficial encephalitis. This consists of an inflammatory swelling of the surface of the brain and is indicated at the operation by the immediate protrusion of the brain substance into the incision made through the dura.

Serous meningitis not rarely occurs as a preliminary stage of tuberculous meningitis. It may precede the tubercular form some weeks or months. With serous meningitis, as a preliminary stage of tuberculous meningitis, the pressure of the cerebrospinal fluid is unchanged, whereas it is always increased in ordinary serous meningitis. In these cases it would be necessary in making lumbar puncture to measure the pressure under which the cerebrospinal fluid is evacuated. This is best done by one of the usual manometers, for instance, Sahli's. The pressure in a meningitis serosa occurring as a preliminary stage of tuberculous meningitis will be found to be normal or not essentially increased.

(To be continued.)

Reports of Societies.

AMERICAN PSYCHO-PATHOLOGICAL ASSOCIATION.

FIRST ANNUAL MEETING, WASHINGTON, D. C., MAY 2, 1910.

SEX SYMBOLISM IN DREAMS.

DR. JAMES J. PUTNAM, of Boston, described, with examples, the remarkable symbolism of the dreams into which sexual emotions enter. As in all dreams, so here, the imagery employed serves at once to reveal and to conceal the emotions that are at work, whether these are related directly to sexual acts or only indirectly. It is a remarkable fact that, although the dream, in general, reflects thoughts and feelings that must be more or less continuously present, even during waking hours, much of the imagery seems foreign to our waking thoughts. The explanation of this is found in the facts that point to the occurrence of unconscious thinking. That is, neither the dream-emotions nor the dream-thoughts are really foreign to our waking thoughts, but they are studiously repressed and suppressed. By a study of these dreams, a great deal of light is thrown on the secondary sexual emotions and their relation to ideas of death, violence, pain, fertility, prenatal life, etc. Many of these ideas belong, in their most striking form, to the mysterious and remarkable period of childhood; and this period is reilluminated by our dreams.

It was decided to have the other papers read and have all discussed together.

THE ACTION OF SUGGESTION ON PSYCHOTHERAPY.

DR. ERNEST JONES, of Toronto, said that the term "suggestion" covers two processes, "verbal suggestion" and "affective suggestion," of which the latter is the more primary and is necessary for the action of the former. Affective suggestion is a *rapport* that depends upon the transference of certain positive affective processes in the unconscious region of the subject's mind. These are always components or derivatives of the psychosexual group of activities. The occurrence is a normal one, but takes place in an excessive degree in the psychoneuroses on account of the presence here of desire that finds no adequate outlet. It is one form of the more general mechanism of "displacement" by means of which an affect is transposed from an original, unpleasant and "repressed" idea to another less inacceptable one. Suggestion plays the chief part in all methods of treatment of the psychoneuroses, except the psycho-analytic one. It acts by releasing the "repressed" desires that are finding expression in the form of symptoms, and allowing them to become attributed to the idea of the physician's person. Psychologically, this means the replacement of one symptom by another, namely, psychosexual dependence on the physician. This is often of temporary, and sometimes of permanent, benefit, but in severe cases the replacement is both inconvenient and detrimental. In psycho-

analysis, the "repressed" desires are permanently released by being made conscious and, hence, can be directed by "sublimation" to more useful, non-sexual social aims.

THE ANXIETY NEUROSES.

Dr. A. A. Brill, of New York City, then read a paper on this subject, in which he said that this symptom-complex was first described by Professor Freud, who separated it from neurasthenia. The causative factors of the disease are somato-sexual injuries. The cardinal symptoms are attacks of anxiety, anxious expectations, irritability and phobias. Besides the pure anxiety neurosis, there is a mixed type, namely, anxiety hysteria. In this, the psychic mechanisms are the same as in hysteria, but instead of the characteristic conversion of the psychic into the physical, there is anxiety. The anxiety is, so to say, the only symptom into which the psychic excitement is converted. To illustrate this type of neurosis, Dr. Brill cited a very interesting case. It was that of a woman, thirty-eight years old, who suffered with periodic depression resembling manic-depressive insanity. By the analysis of a dream, the whole mechanism was discovered, and the patient cured. This case showed the importance of entering into the sexual life and the analysis of dreams.

THE MECHANISM OF DREAMS.

Dr. Morton Prince, of Boston, presented a paper based upon the analysis of a considerable number of dreams in a subject who was particularly favorable for observation. The dreams were observed in unusual detail in hypnosis. In the same way, the associative memories connected with each detail of the dream were obtained, the memories of several hypnotic states, as well as of the normal state, being used. The conclusions arrived at supported the theory of Freud up to a certain point, viz., that there are two dream processes, that of the dream consciousness, which Freud terms the "manifest" dream, and an unconscious process, which is one seen in the dream or motivating process. The latter Freud terms the "latent" dream. The conscious dream symbolized the unconscious dream-process. The motive of the dream could in every instance be traced to strongly organized systems of ideas, which were deeply rooted in the mind of the subject. The material of the dream that the unconscious motive made use of in the construction of the conscious dream could always be found in the recent thoughts of the subject, particularly those passing through the mind just before dropping into sleep. The conscious dream, being a patchwork of this material, was not a literal reproduction of the motivating thoughts, but consisted of sensory hallucinations that only symbolically represented these sleep-rooted thoughts. A dream is, therefore, only a particular type of hallucinatory symbolism. It does not stand by itself as an isolated phenomenon. If the theory that a dream is the resultant of two processes, one unconscious and the other conscious, be true, said the author, then we ought to find evidences of the same mechanism in other types of hallucinatory symbolism. Symbolism, as an hallucinatory phenomenon, occurs in numerous and multiform conditions; and a study of these shows evidence of these same two processes being at work.

(1) The simplest form is the visual hallucination of a number, evidenced by pinching the anesthetized skin of hystericals and their symbolizing the number of pricks.

(2) Artificial and spontaneous hallucinations, which represent symbolically scenes or experiences in the life of the individual.

(3) The hallucinations occurring in sudden religious conversion, which symbolize the previous thoughts of the individual; also those which symbolically answer previous doubts, fears or questions, or represent the "prickings" of conscience.

(4) Suggested post-hypnotic phenomena, such as calculation experiments in which visual hallucinations of numbers come into the mind consciously or subconsciously. These numbers must arise as the result of an unconscious process.

(5) Hypnagogic hallucinations.

All these forms of hallucinatory symbolism can be explained, Dr. Prince asserted, only on the hypothesis of a mechanism that includes an unconscious process (the motivating thoughts) and a conscious process (the hallucination). This hypothesis of dreams, therefore, is in entire accord with that of analogous phenomena.

The writer had been unable to confirm Freud's conclusions in other respects, e. g., that dreams always represent the fulfillment of a wish. On the contrary, he said, a dream may be the non-fulfillment of a wish or the fulfillment of fears, anxieties, etc. As to the exact mechanism by which the unconscious process translates itself into the conscious symbolism, he considered this a matter for future investigation.

DREAMS AS A CAUSE OF SYMPTOMS.

Dr. G. A. Waterman, of Boston, presented a series of dreams illustrating how the prominent emotional conflict of the life of the patient was symbolically represented in the dreams of the individual and gave rise to physical disturbances persisting for days or months. In the analysis of these dreams, it was shown how the explanation of the mechanism to the patient was followed by a disappearance of the symptoms.

Discussion on the five foregoing papers was opened by Dr. Isador Coriat, of Boston, who said that he believed that the Freudian theory had been carried too far in placing all these dreams on a sexual basis, Freud's only reasons for claiming that they have a sexual basis being the deep-seatedness of the sexual instinct and the fact that it may be traced back to the earlier years of life. The speaker thought, however, that these fancies might have a thirst or a hunger element, because the hunger and thirst instincts are just as much a part of our lives, and can be traced as far back, as the sexual instinct. He found that a great many dreams that lie in the unconscious or the conscious life can be traced by the pulse-reaction. In a number of cases, he had given words that he believed to be indifferent to the patients, and had obtained a very marked reaction. Through the use of various psycho-analytic methods, he had traced out the relation of these words to the patient's dream life, and he had found that many of these sexual feelings may go back to early childhood. In one case, they went back to the age of three years, but there were other somata in this case, and not the sexual alone. He stated his belief that hypnosis can do more than some claim, and said that it is nothing but an artificially produced form of absent-mindedness. Every one of the phenomena of hypnosis may be found in normal absent-mindedness — particularly increased suggestibility.

Dr. John Donley, of Providence, stated that he had recently had under his charge two interesting cases. One was that of a woman who had been crossing the street when a car bore down upon her. As she tried to pass, the motorman shouted violently, and she immediately felt pain in her head, shooting down her back and into her arms. This pain disappeared, but it would recur after irregular intervals, no medical treatment being of any avail. He tried to find out the basis of the trouble by means of hypnosis and discovered that she was having dreams in which she was hallucinating the

whole process. The day after each of these dreams the pain would recur in precisely the same situations as just after the accident. She would also dimly remember that she had dreamed during the previous night, but would not ascribe the pain to the dream. After three months of reproducing the dream, and explaining it away, Dr. Donley found it possible to relieve her.

The other case had reference to the transference of affective states in the genesis of an obsession. A young man, twenty-one years old, could not attend the theater with any comfort on account of having a feeling of panic, palpitation and distress each time he went. When he was six years of age, his mother had died, and he was taken under the care of an aunt. She treated him rather roughly, so that he never felt any love for her. This made him feel the loss of his mother very deeply. He would brood upon it, and would cry after going to bed, and this produced a more or less subconscious affective condition to exist all the time. One day, he went to the theater to see a melodrama. One of the scenes in this play suggested to him the loss of his mother, through association of ideas, and he became so uncomfortable that he had to leave the theater. The result was that he transferred his affective state of fear and discomfort from the loss of his mother to the theater, and whenever he would subsequently enter a theater, particularly this one, he would have the same difficulties that most people have in any obsession.

DR. TOM WILLIAMS, of Washington, D. C., thought that the reason given by the first speaker for refusing to accept exclusively the sexual genesis of dreams was not convincing, and said that the sensations of hunger and thirst are quite different from the sexual, in that the former are purely personal, while the latter is sociological. He admitted that some neurologists have sought to attribute too exclusively to sexuality many psychoses that he had found susceptible of being engendered through other affective disorders. He considered the fundamental explanation of these to be connected with the shame reflex that is bound up with the idea of sex. He stated that the same affect belongs to other sociological conditions, such as those connected with dishonesty, untruthfulness, etc. He had had cases in which it was entirely due to these, especially an instance in which there seemed to be no abnormal sensual affects, the whole syndrome being caused by the repression of expansion in social activities. Dr. Williams agreed with Dr. Prince in thinking that the dream is only one avenue toward obtaining a knowledge of psychic life, and said that he had very often been able to gain the same information without the aid of dreams. As a matter of fact, he considered the effort necessary in order to obtain a recollection of dreams to be as great, in some cases, as the effort of recollecting the factors in the mechanisms that have determined the psychoses. His custom is to place his patients in a position in which he can induce them to think of the kind of things that he wishes. He does not suggest thoughts to them, but turns their thoughts in certain directions and endeavors to gain a better knowledge of the processes that are taking place more or less unconsciously in these patients' minds.

Dr. Williams was glad to have heard Dr. Jones call attention to the two elements in the process of suggestion, — the purely ideal and that which pertains to activity, — but he did not agree with that author in believing that the occurrence of ideas depends entirely upon the patient's disposition. He thought that they sometimes occur in spite of an unfavorable affective condition on the part of the patient.

DR. JONES said that it would be well for neurologists to be as precise as possible in the matter of technology. Several of the speakers had used terms in other senses than those in which they are employed in Freud's work. For instance, Dr. Donley had described a case of what he termed "obsession," but Dr. Jones doubted whether any other psychologist would apply that term to such a state, which was really an anxiety state or a phobia. Then another speaker had referred to studying cases by various psycho-analytic methods. Dr. Jones suggested that it would be better to have said, "methods of psychological analysis," "psycho-analysis" being a term invented by Freud to designate one particular method of treatment. In the same way, Dr. Prince had used the word "complex" to describe a process quite different from that meant by Freud when using this term. Dr. Jones thought that Dr. Prince should invent a word to describe his process, and not use the term employed by some one else to indicate something quite different.

DR. PUTNAM did not think that Freud had meant to belittle the importance of other emotions when formulating his sexual theory; neither did he believe that there was any especial conflict among the different methods of investigation and treatment to which reference had been made. He said that Freud's method is, however, susceptible of a more general application than is any other. In connection with the therapeutic difference between Freud's method and others, Dr. Putnam compared it to the difference between exogenous and endogenous trees, and said that it was important that the growth and expansion of human beings should take place interstitially. He believed that, as Dr. Prince had said, memory alone is insufficient to explain all that goes on in the mind during sleep, and thought that Freud also accepted that view, that author having positively stated that the dream is not a sleeping phenomenon alone, but is prepared for during the waking life of the daytime. Dr. Putnam did not consider that anything was to be gained by adopting the conception of residual brain processes, which Dr. Prince had appropriately termed "neurograms," but thought that there exists in the mental life sufficient to afford means of explaining all the manifestations that occur during natural or artificial sleep. He said that memories remain a real mental possession more or less independently of the brain, and suggested that the whole process described by Dr. Jones might be referred to a still deeper process, which might be spoken of as obedience to the law of least resistance. This he thought was what the patient really does in transferring these affections and desires from one person to another.

DR. PRINCE said that he had found the word "complex" used frequently in a sense different from that in which it is employed by Freud, and even by authors who wrote before Freud, that he was inclined to think that this author could not claim it as his exclusive property.

DR. JONES made a motion that a committee on terminology should be appointed by the chair. The motion was seconded and carried.

DR. MORTON PRINCE had acted as President *pro tem.* during this session. He was elected President for the ensuing year. DR. G. A. WATERMAN, of Boston, was elected Secretary-Treasurer. The official name adopted after considerable discussion was the American Psycho-Pathological Association.

Book Reviews.

A Textbook of the Diseases of the Heart and of the Blood Vessels. By DR. ERNST ROMBERG, Professor and Director of the Medical Clinic in Tübingen. Second edition. Stuttgart: Ferdinand Enke. 1909.

This new edition of Romberg's well-known work can be highly recommended both to students who require a clear and complete statement of its subject, and to practitioners of medicine who desire an authoritative opinion and a clear description of recent advances in the study of circulatory diseases. Although the general form of the first edition has been retained, all matters of more recent publication have been so embodied in the text as to give the impression of an entirely new work. The literature has evidently been studied with extreme care that nothing of importance might be overlooked. The bibliographies are full and thoroughly up to date. Of the newer matters described may be mentioned the work of Aschoff and Tawara upon the functional anatomy of the heart, the work of Erlanger, Hering and others upon the pathological physiology, Eithoven's electrocardiogram studies, the percussion methods of Goldscheider and others, controlled by the orthodiagram, and Mackenzie's clinical investigations by means of simultaneous tracings of venous and other pulsations. Korotkow's method of determining diastolic blood pressure is mentioned with favor. The arrhythmias are discussed according to Hering's classification. But far from laying too much stress upon newer discoveries, the bulk of the work deals with the older and better established methods of diagnosis and of treatment. It may be noted that warning is issued against a too-ready acceptance of the intravenous use of strophanthin. This and other statements illustrate the tone of sound conservatism which prevails throughout, in which one cannot fail to recognize the good judgment and well-deserved authority of the author.

Studies in Immunity. By Prof. Paul Ehrlich and his collaborators. Collected and translated by Dr. Charles Bolduan. Second edition. Octavo. Pp. 712. New York: John Wiley & Sons. 1910.

The appearance of a second edition in English of Ehrlich's fundamental studies in immunity is the best evidence of the relatively widespread interest in so technical a work. The first edition appeared in 1906 following the original German edition prepared by Ehrlich. This new edition, to which no German analogue exists, contains the work embodied in the first edition and a number of papers which have appeared since that time. These additional papers include particularly certain articles which are discussed in the recently published "Studies" of Bordet prepared by his pupil, Gay. The combination of these two volumes includes the larger part of the essential advances in immunity for the last fifteen years, and a comparison of the two schools of thought evidences the value of fair-minded, scientific antagonism.

The present edition of Ehrlich is greatly benefited by the addition of helpful indices.

Surgical After-Treatment. A Manual of the Conduct of Surgical Convalescence. By L. R. G. Crandon, A.M., M.D., Assistant in Surgery at the Harvard Medical School; Assistant Visiting Surgeon to the Boston City Hospital; Consulting Surgeon to the Frost General Hospital. With 265 original illustrations. Philadelphia and London: W. B. Saunders Company. 1910.

Of the numerous books on after-treatment which have come from the press during the past two years, Crandon's is probably the best. He professes to write for house surgeons and general practitioners, but in fact his book commends itself to all surgeons who have a proper regard for the comfort of their patients in convalescence. The author acknowledges his obligations to Dr. Albert Ehrenfried, whose "enthusiastic assistance has amounted to collaboration"; to Dr. George P. Sanborn, who has written the chapter on Vaccine Therapy; to Dr. Frank B. Granger, who has contributed the section on electrotherapy; and to sundry other physicians and surgeons connected with the Boston City Hospital and Harvard Medical School.

The book is refreshing, stimulating and instructive from many points of view. For example, the first chapter, on the sick-room and the nurse's duties, is unusually good, while the illustrations of the various positions to be assumed by patients are valuable. The chapter on anesthesia is admirable, especially on that feature of the anesthesia most distressing to the patient, the recovery. One wishes only that more might have been said regarding the striking advantages of gas and oxygen when used as a routine anesthetic. Thirst, pain and sleep, the significance of the pulse, temperature and respiration, are well treated, while the chapters on hemorrhage, transfusion, shock, collapse, coma and sudden death are most informing.

Our space is too limited to dwell in detail on the numerous excellent features of the book, especially on the care of patients after abdominal operations, but one cannot pass by without mention the suggestions regarding certain details of treatment after special operations. For example, the essay on the recovery from thyroidectomy contains all the best recent conclusions of well-known operators, while the author's treatment of persons convalescing from hernia, appendicitis and general peritonitis is entirely satisfactory. One is surprised, perhaps, to find so much said regarding the surgery of orthopedic lesions, — operations on the bones and joints especially, — but every general surgeon must deal with such lesions, and he will do well to read these chapters.

It would be easy, obviously, to differ from the author in many of his procedures and conclusions, but such differing would amount to a discussion of details only and would not affect the value of the book as a whole. Not the least interesting feature of the work is the appendix, which suggests to the surgeon and the nurse a list of invalid foods and recipes. The illus-

trations, mostly photographs, are excellent, and the press work is of the best. We cordially endorse the work and commend it to the profession.

Manual of Tropical Medicine. By ALDO CASTELLANI, M.D. (Florence), Privat-Docent Naples, and ALBERT J. CHALMERS, M.D. Vic. and Liv., F.R.C.S. Eng., D.P.H. Cantab. University Series. New York: William Wood & Co. 1910.

This volume, representing the personal experience of the authors in Asia and Africa, is a valuable addition to the textbook literature of tropical medicine. Of particular interest are the chapters in the second part describing tropical poisons, poisonous weapons and foods, and venomous animals. The clinical section, on the diagnosis and treatment of tropical diseases, is complete, succinct and thorough. The book is illustrated by 373 figures in the text and 14 colored plates. As a whole, it presents in lucid and compact form a vast amount of description, observation and useful information which should make it of great value as a work of reference to any physician who purposes to teach or practice tropical medicine.

Diseases of the Stomach and Intestines. By ROBERT COLEMAN KEMP, M.D., Professor of Gastro-Intestinal Diseases in the New York School of Clinical Medicine; Visiting Gastro-Enterologist to the New York Red Cross Hospital, etc. With 280 illustrations, some in colors. Philadelphia and London: W. B. Saunders Company. 1910.

This volume deserves high commendation as an exhaustive description of the most modern methods of diagnosis and treatment which have been advocated in the management of gastric and intestinal cases. The chapters on special methods of examination and of treatment are of interest since they demonstrate procedures of great ingenuity which have been practiced as yet only in a limited number of clinics. The individual diseases are also thoroughly considered, especially with reference to treatment. The work is encyclopedic in the number of disorders, both organic and functional, which are discussed. Although many diagnostic and therapeutic measures mentioned have not yet received general acceptance, and some are of too complicated a nature for widespread employment, these special methods are not given prominence to the exclusion of procedures applicable in ordinary practice. The book can be recommended, therefore, both to the general practitioner, who will find in it many useful suggestions, and to the specialist who is able to make more elaborate investigations.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 1, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE NURSING SPIRIT.

THERE seems at present to be so much uncertainty regarding the amount of training a nurse shall receive, and the nature of that training, that a recent article by W. C. Graves,[1] executive secretary of the Illinois Charities Commission, is of more than usual interest.

Mr. Graves declares that in caring for the sick, as in any other art, a spiritual fitness for the service is necessary to attain success, and that in a nurse this is more essential to the relief and cure of a sick person than the same quality in a physician. The nurse is with a patient practically all the time; the physician, as a rule, sees the patient at intervals, and then only for a short space of time. Hence, the nurse who wishes to succeed, in the largest sense of the word, must have the genuine nursing spirit; she must enjoy caring for the sick; she must receive her greatest compensation in the realization that persons are restored to health and the pleasures of life as the result, at least in part, of her care and ministrations, and that those who die pass into the Great Beyond soothed by the knowledge that a sympathetic watcher is with them. Mr. Graves compares the ultrascientific nurse who performs her duties with religious fidelity and machine-like precision, but with absolutely no personal interest in her patient, with the "Heaven-sent creature whose gentle touch and whose encouraging words are added to scientific ministration as an anodyne for the troubled heart and a stimulant for the apprehensive spirit."

These are strong expressions, from a layman's standpoint, which are quite worthy consideration. Instead of teaching nurses laboratory

[1] Ill. Med. Jour., August, 1910.

work, — chemical and bacteriologic, — the feeling at times arises, whether it would not be better to devote more time to training them in the actual care of the patient. Florence Nightingale, the greatest nurse the world has ever known, concerned herself solely with the comfort of the patients. Why, then, should the modern trained nurse consider as beneath her anything which makes for the patient's wellbeing?

In private practice, the nurse should be able to keep her patient cheerful and amused, and she should be willing and able to converse on current topics with those who are convalescent. But how many nurses do this? In the majority of cases, the course of the disease is materially affected by the mental outlook of the patient, and a nurse with the "nursing spirit" will be of inestimable aid to the physician, while the machine-like nurse trained essentially in laboratory and operating-room technic (practically never needed outside of hospitals) may well prove a decided obstacle to the patient's speedy recovery.

We are not advocating employment of untrained nurses, — far from it; simply a different or modified course of training. After all is said and done, the nurse's chief duty is to carry out the orders of the physician, and her training is to enable her to do this intelligently. In large hospitals where the nurses are frequently overworked, it is impossible to give each patient the care and attention which a nurse would be expected to give a patient in private practice. Under such conditions, the nurses necessarily become machine-like in their methods, especially if they lack the true nursing spirit, or what Mr. Graves calls the "mothering instinct."

CONGESTION OF POPULATION IN NEW YORK.

On Aug. 25 the Mayor's Commission on Congestion of Population in New York was addressed, at a meeting held at the City Hall, by Prof. Stanley D. Adshead, director of the Department of Civic Design in the University of Liverpool. While complimenting the city of New York on many of its developments, he stated that the overcrowding in Manhattan was much greater than in any European city. This, he thought, was due indirectly to the peculiar position and shape of the island, and directly to the immense value of the land and the lack of foresight on the part of the public authorities in the past. He expressed the opinion that, as had already occurred in Berlin, Frankfort and Düsseldorf, and was now imminent in London, Manchester and Liverpool, there would be in New York a collapse in the value of property, which is held up artificially by reason of the lack of restrictive measures and inadequacy in measures for distributing the population. Having remarked that the standards at present set by New York as regards light and air in tenements were too low, and the number of inspectors employed by the tenement-house department far too small, Professor Adshead said that the solution of the New York problem appeared to him to be to advocate, as far as possible: (1) The removal of all factories and business establishments out of the restricted area of Manhattan wherever such business can be carried on elsewhere. (2) To encourage in every possible way the construction of more arterial lines of communication, particularly by subway. (3) To open up all undeveloped and desirable building land within twenty miles of the city of New York by constructing new lines of communication, and so decentralizing the city, and at the same time, but not before, to enforce stringent and restrictive measures on the use of land in Manhattan. This may bring about a temporary collapse, but any such collapse will ultimately be followed by a recovery which will be brought about by a more advantageous use of the land. Alterations in the use of or restrictions put upon land should be made as gradually and carefully as possible; the medical operation of drawing the sore is less harmful than the surgical one of removing it.

DR. FLEXNER'S REQUEST FOR POLIOMYELITIS MATERIAL.

In another part of this issue we publish a letter from Dr. Simon Flexner asking assistance in securing specimens of the nervous system from fatal cases of poliomyelitis. Apart from any other consideration, Dr. Flexner's researches have reached such a point that every possible assistance should be rendered him in bringing his promising investigations to a wholly satisfactory conclusion. While very much remains to be determined regarding the etiology and nature of the organism concerned, and the possibility of providing an antitoxic serum, it is evident to those who have followed the subject that the possibilities of the future are great and that results of positive importance are likely to issue from Dr. Flexner's laboratory in view of the work already accomplished there. It is also manifest that the essential means of prosecuting the research to its conclusion is material from early cases of polio-

myelitis. If those physicians who are seeing these cases and who are able to procure a post-mortem examination would unite in forwarding their material to the Rockefeller Institute as requested by Dr. Flexner, there is no question that it would there be used to the greatest possible advantage. We therefore urge physicians not only to secure post-mortem examinations if possible in these cases, but also to preserve and forward the material as early as may be to Dr. Flexner and his associates in New York.

GOVERNMENT ADVICE AS TO THE KEEPING OF DIPHTHERIA ANTITOXIN.

IN Bulletin No. 66, issued in June, 1910, from the National Hygienic Laboratory, Anderson reports a very opportune piece of research on "The Influence of Age and Temperature on the Potency of Diphtheria Antitoxin." It appears that in the past manufacturers of antitoxin have been much in the dark as to the length of time in which their product may be safely kept. Most of them have recalled sera more than nine months old, while some have allowed it to be marketed for one year from the date of its preparation.

By keeping samples of sera from various sources under different conditions, and testing an unbroken package from each set every six months, Anderson found that the average yearly loss in potency of diphtheria antitoxin at room temperature is about 20%; at 15° C., about 10%; at 5° C., about 6%. He found but little difference in the decrease of potency in unconcentrated sera and in those concentrated by the Gibson method. Preservatives seemed to have no effect.

He advises, therefore, that diphtheria antitoxin to be placed upon the market and kept under unknown conditions as regards temperature, should be labeled to be returned within two years and should contain an excess of at least 33% to allow for decrease in potency. He suggests tentatively that perhaps the older a serum is, the less will be its likelihood to cause severe serum reactions.

MEDICAL NOTES.

CULTIVATION OF THE BACILLUS OF LEPROSY.— It is announced from Washington that Dr. Walter R. Brinkerhoff, Dr. Donald H. Curry and Dr. H. T. Hollman working together have succeeded in growing the bacillus of leprosy in pure culture. If this report be substantiated, it evidently paves the way for a rational treatment of this still widespread and fatal disease.

THE CHOLERA SITUATION. — Cholera has diminished in Russia, and it appears on further investigation that the suspected cases in Berlin have proved not to be cholera. There are but two authentic cases in that city, presumably due to Russian immigrants. A number of suspicious cases are under observation at the Virchow Hospital.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Aug. 30, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 32, scarlatina 19, typhoid fever 24, measles 11, smallpox 0, tuberculosis 68.

The death-rate of the reported deaths for the week ending Aug. 30, 1910, was 17.22.

BOSTON MORTALITY STATISTICS. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Aug. 27, 1910, was 221, against 201 the corresponding week of last year, showing an increase of 20 deaths and making the death-rate for the week 18.30. Of this number 116 were males and 105 were females; 215 were white and 6 colored; 141 were born in the United States, 79 in foreign countries and 1 unknown; 44 were of American parentage, 152 of foreign parentage and 25 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 28 cases and 4 deaths; scarlatina, 18 cases and 2 deaths; typhoid fever, 33 cases and 3 deaths; measles, 16 cases and 3 deaths; tuberculosis, 70 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 12, whooping cough 0, heart disease 25, bronchitis 1. There were 18 deaths from violent causes. The number of children who died under one year was 45; the number under five years, 72. The number of persons who died over sixty years of age was 62. The deaths in public institutions were 95.

Anterior poliomyelitis, 2 cases.

Of the above infectious diseases the following were non-residents: Consumption, 4 cases and 4 deaths. Typhoid fever, 1 case and 2 deaths. Scarlet fever, 4 cases. Anterior poliomyelitis, 1 case.

Deducting deaths of non-residents, the total is 189 and the death-rate is then 15.65.

GLANDERS IN LYNNFIELD, MASS. — It is reported that three horses in Lynnfield have

died of glanders. A quarantine has been instituted which will, no doubt, prevent the spread of the disease.

Work of the Floating Hospital. — It is reported that Baltimore is about to undertake work similar to that of the Floating Hospital. Dr. R. M. Bruns, a physician of that city, has been investigating the methods of the hospital and will later study the work in New York in the expectation of inaugurating such a hospital in Baltimore.

State Investigation of Infantile Paralysis. — The Massachusetts State Board of Health publishes in this month's bulletin the results of an investigation by Hennelly and Sheppard of the cases of infantile paralysis occurring during 1909 and 1910.

This investigation disclosed nothing of moment as regards the spread of the disease, save that it appears equally by the sea and inland, in crowded centers and in those thinly populated. Of 150 cases carefully studied, 62 were swimming or wading, just before the onset, in water contaminated by sewage. The report also calls attention to the fact that several instances are recorded where children not exposed to the disease, but intimate with others who had had attacks as many as twelve years previously, had contracted infantile paralysis. The presumption is strong that this is a coincidence merely.

The report concludes with a statement of symptoms and methods of treatment, written by six physicians who have had much experience with the disease.

NEW YORK.

A Centenarian. — John Kipp died in the Warren County almshouse, near Oxford, N. J., on Aug. 19, at the age of one hundred and three years, having been born, it is stated, on Dec. 6, 1806. Three years ago he sustained a fracture of the hip, since which time he has been confined for the most part to bed.

Poisoning by Lysol. — A case of poisoning by lysol similar to the recent case in New Jersey has just occurred in New York. Dr. T. A. Gonzales, of Lexington Avenue, gave a prescription calling for "laxol" for a baby one year old. The druggist's clerk who put up the prescription mistook the word for lysol, and a teaspoonful of this was given to the child with fatal results.

Discontinuance of Straus Milk Depots. — Word has been received from Nathan Straus in Berlin that, after the present season, owing to certain criticisms of the work, he will discontinue his stations for the distribution of pasteurized milk in New York. It is stated, however, that this philanthropic work will be continued in Washington and in the several German cities where he has instituted the milk depots. There are, at present, seventeen Straus milk stations in New York.

Bequests. — Among the charitable bequests in the will of the late Mrs. Harriet Coles, of Glen Cove, Nassau County, N. Y., is one of $7,500 for the founding of a free bed in the Presbyterian Hospital, New York.

Among the bequests in the will of the late Mrs. Flora L. Dotger, widow of Andrew J. Dotger, of East Orange, N. J., are $10,000 each to the Orange Memorial Hospital, the Orange Bureau of Associated Charities, and the German Hospital of Philadelphia.

Gangrenous Ergotism. — Five members of a family living in the Fort Washington district of the city have been attacked with a disease extremely rare, if not entirely unknown, in the United States, gangrenous ergotism, and two of the patients are being treated at the J. Hood Wright Memorial Hospital. The Health Department is making an investigation, especially with a view to discovering the source from which the bread infected by the parasitic fungus which was eaten by the family was obtained.

A Check to Osteopathy. — In their efforts to secure official recognition, the osteopaths met with another defeat on Aug. 26, when Justice Putnam, in the Supreme Court, Brooklyn, decided that the Health Department was within its rights in refusing a burial permit where an osteopathic practitioner had attended the deceased. Since the legislature passed a law recognizing the osteopaths in the state of New York, the courts have sustained their right to practise, but, under a new section of the Sanitary Code, they have been denied the privilege of issuing death certificates. Acting on this provision, the Health Department filed a demurrer to their complaint, and, in sustaining the demurrer, Justice Putnam said, "While the state has allowed the practice of osteopathy, it does not follow that it thereby holds one without any practise in surgery or experience in prescribing drugs as fully qualified to certify the cause of death. Granted that the theoretical education of the osteopath is of a

standard equal to that of a doctor of medicine, after he enters on his profession his practice is restricted; so that it does not appear that he can make the tests, by examination of the blood and tissues, by which alone many diseases can be certainly determined. The Sanitary Code is discriminating, but the discrimination is not personal or arbitrary. It is based on a limitation which the osteopath may be said to make for himself, and which deprives him of no rights he ought to exercise consistent with the public safety."

14. Flexner and Lewis report in their eighth paper the following findings on experimental poliomyelitis in monkeys: It can now be accepted as established that human beings and monkeys who have passed through an attack of poliomyelitis have come to contain in their blood certain neutralizing principles for virus of poliomyelitis; that these principles are readily demonstrated by animal tests for two or more years in humans, and that they probably exist for as great a period in monkeys. It has been shown that monkeys who have recovered from an attack of poliomyelitis are highly refractory to reinoculation with the virus, and it is probable that human beings are similarly protected from reinfection. It has been possible to make monkeys immune also by injecting the virus subcutaneously. This mode of producing immunity is, however, not yet perfected, as some of the animals do not develop a strong immunity and others develop paralysis as a result of the treatment. When an active filtrate containing virus is mixed with serum of actively immunized monkeys and incubated for a period at 37° C. it no longer sets up paralysis on being injected into the brain of normal monkeys. Serum derived from children who have passed through an attack of poliomyelitis has been shown to possess some therapeutic value in monkeys, for when subarachnoid injections are begun twenty-four hours after the intracerebral inoculation of the virus, the development of paralysis can be entirely prevented in a certain number of the animals, while in others the onset of the paralysis is much delayed. Neutralized mixtures of virus and immune serum do not lead, however, to any degree of active immunization.

6. HUNT, J. R. *The Symptom-Complex of the Acute Posterior Poliomyelitis of the Geniculate, Auditory, Glossopharyngeal and Pneumogastric Ganglia.*

1. This article is an attempt to settle the definition of "inflammation," and to substantiate by proof the various stages of the process. Opie holds that "inflammation is the process by means of which cells and serum accumulate about an injurious substance and tend to remove or destroy it. This process does not include the regenerative changes which replace injured tissue by newly formed parenchymatous elements or by new interstitial tissues." The communication, tracing the phenomenon of inflammation throughout the animal kingdom, presents a definite, comprehensive description of this fundamental process.

4. Krumbhaar reports a case of long-continued Adams-Stokes' syndrome and complete heart-block which at autopsy showed no lesion of the bundle of His. Beyond suggesting that the heart-block may have been due to fibrosis of the sino-auricular bundle of Keith, he offers no explanation of this rare condition.

5. In an extensive research on the metabolism of bones, especially with regard to osteomalacia, McCrudden has reached some very definite conclusions. He shows that, until late adult life, an active process is going on in bones. In rickets, the newly formed bone is deficient in lime. In osteomalacia, the supply of calcium necessary to keep the quality of the bones up to normal falls short, and the typical condition of bone-weakness develops. He refutes the theory that lactic acid in the blood is responsible for this, and shows that the theory of an obscure ovarian influence is unsound. The disease, he holds, is due to the withdrawal of calcium from bone metabolism, due to a demand for it elsewhere, as for the fetus. Thus he explains not only the fact that osteomalacia occurs oftenest in women who have had several pregnancies in rapid succession, but also that in pregnant women there may be a tenderness of the pelvic bones. The occasional occurrence of this disease in unmarried women and in men he touches rather lightly, suggesting that bony deposits in some abnormal part of the body

may be the cause. Hygiene and the prevention of pregnancy he considers the main factors in treatment.

3. FRANCINE, A. P. *Intrathoracic Displacements in Pulmonary Tuberculosis.*
4. *STROUSE, S., AND CLOUGH, P. W. *Blood Cultures in Pneumonia.*

1. Henderson describes a series of experiments in support of his theory that many deaths supposedly due to what is known as "surgical shock" with the accompanying low blood pressure are not really due to shock, but to a simple failure of the respiratory center to continue its function. This center, as is well known, is stimulated to action and continuance of its efforts by the presence of CO_2 as an irritant. The effect of any severe pain is to produce a type of deep breathing which soon overoxygenates the body and greatly decreases the amount of CO_2 which should be normally present. This when carried to an extreme results in a failure of the respiratory center to act, with death as a result. He elucidates this theory at some length.

4. Strouse and Clough obtained positive blood cultures in 14 out of 25 cases of pneumonia. They report the work of others on this subject and present their own views in tabular form. They conclude that in certain epidemics blood cultures in pneumonia are positive in a majority of all cases, but in such cases the results have no prognostic value. [J. B. H.]

4. Paul considers that prostatic hypertrophy is not due to a chronic inflammation of septic or specific type, nor to a neoplasm, but that it is an involution change similar in character to that which occurs in the mammary gland. He presents his evidence at length in support of this theory.

5. Whyte has made a study of the eosinophilia accompanying the infection of the intestinal tract by various worms. The eosinophiles increase along with the increased numbers of this infecting organism. Patients over forty years showed a less degree of eosinophilia than those younger. The more varieties of parasites infecting a single individual, the greater the eosinophilic reaction.

10. Ewart urges the earlier diagnosis of tuberculosis in children. The ideal condition would be to make such a diagnosis in the so-called "pre-tubercular" stage, but as many other conditions, such as adenoids, enlarged tonsils, poor teeth, malnutrition and anemia may simulate a pre-tubercular one, this is in many cases impractical; he is of the opinion, however, that by finer methods of diagnosis and chest examination the condition which he calls "pre-pulmonary tuberculosis" should be diagnosed earlier than it now is. He discusses the various signs and symptoms which he and others consider of value. (The writer's general idea is undoubtedly a correct one, but the term "pretubercular" is an unfortunate one.)

8. ARNOLD, W. T. J. *Turpentine Enemata in the Treatment of Enteric Fever.*

2. Philip and Porter describe their method of staining for tubercle bacilli in the feces in cases of pulmonary and other forms of tuberculosis. One hundred and nine different specimens were examined, 99 of which were from cases of phthisis and in only 34 of which had bacilli been found in the sputum. Of these cases, 79 were found to yield tubercle bacilli; all of those with bacilli in the sputum showed bacilli in the feces; of the 24 cases without sputum, 17 showed bacilli in the stools. As means of early diagnosis, these results may be of great value; from the public-health point of view the frequency of bacilli in the stools is of great importance.

4. Pearce, Rankine and Arnold present an interesting study of 28 cases of Mongolian idiocy, describing the leading signs, symptoms and characteristics of this condition. Among other striking features is the average short duration of life—fourteen to fifteen years—and the large percentage of deaths from tuberculosis in their series—nearly 100%.

1. Treupel, in his short address, simply endeavors to state the present status of Ehrlich's new arsenic preparation for the treatment of syphilis. The new compound of arsenic — the monochlorhydrate of dioxydiamido-arsenobenzat — may be given intramuscularly or intravenously. After intravenous injection in humans it is not known how long arsenic is excreted by the kidneys. After intramuscular injection, it is excreted from twelve to eighteen days. So far, no harmful results from the inoculations have been reported. At the site of injection there is usually considerable tenderness and reaction. With the symptoms of syphilis the results are most gratifying, as in a few days after one injection the symptoms disappear. Also with parasyphilitic affections the temporary results are gratifying. The permanency of the results and the length of time this treatment should be carried out are points to be decided in the future. [C. F., JR.]

9. GROAG, P. *Studies on Chlorosis.*

1. Lubarsch fed some guinea-pigs with liver, others with adrenal gland, and still others with horse meat. The animals died or were killed at different times, some took the food well and others badly, so that uniform results could not be expected. Many of the pigs fed on liver developed sclerosis. The smaller arteries chiefly were attacked; the disease began in the media and calcification occurred. The animals fed on adrenal gland showed similar changes in a less degree, and those fed on horse meat showed no vascular change. The writer says that the sclerosis which he produced does not resemble human arterial changes as closely as did that obtained by injecting bacteria or by adrenalin. He believes that human arteriosclerosis has a multiple etiology, that there are several varieties of it, that it is a degenerative, sometimes partly inflammatory, disease, and that it is not a normal or necessary result of age.

3. Tests by the writer seem to show that the Wassermann reaction often fails in cerebrospinal lues merely because insufficient fluid is used for the test. [G. C. S.]

1. The author makes an urgent plea for a wider use of the hand in obstetrics. This is particularly for the general practitioner. He points out the ease with which these simple maneuvers can be accomplished, and what great aids they are in handling difficult cases. The article is illustrated with several diagrams.

2. This paper goes quite fully into the technic of preparing Ehrlich's "Preparation 606." The author also reports a case of apparent cure of congenital syphilis. [J. L. H.]

Miscellany.

WILLIAM JAMES, M.D., LL.D.

A Tribute.

The death of William James — honored teacher, charming companion, loyal and generous friend — calls out a surge of feelings, some of which deserve especial mention in this journal. Dr. James was, above all things, a lover of his fellowmen and deeply sympathetic with them in their troubles, all the more so because of his medical training and affiliations, and made himself beloved in turn by friends and followers of many lands. With all the warmth of a very warm nature, he cared that every one whose needs were known to him should have his best chance — the chance to set himself free, to choose for himself, to develop on his own lines. He rated, indeed, individual liberty and individual development so high that he was always ready to break a lance in their defense at the cost of personal sacrifice, even when in so doing he incurred the censure of many an honored colleague.

Another dominant feature of his character, akin to this and related also to his hatred of everything savoring of tyranny, was his quickness to detect what seemed to him false notes of over-confidence in many schemes, political, intellectual or moral, that claimed to be of universal application, and if he thought it right, he would oppose them, no matter what their age or dignity or by whom supported. Perhaps his remarkable ability trenchantly to expose the flaws in others' reasoning increased his power to see such flaws, but certainly he had an ingrained disbelief in any one's ability to discover any truth so important for mankind as the truth that every one is bound to keep his own vision clear and his own will free. Thus James the man explains and illustrates James the philosopher. Filled with the love of mankind, or, rather, men; ready to advocate unpopular causes; believing that every one should make himself, his own character, opinions, temperament even, count as active forces; suspicious of absolutism under every form, it is not strange that he should have marched, a welcome ally, under the banners of "humanism," "pluralism," "pragmatism," of "free thought" in the best sense. It would be out of place to discuss here the merits of his philosophic views, still less to do what he has never done, — pronounce them final. But they have accomplished what he wished of them, — they have made all men think and helped many men feel a man's glow of manliness and courage. I well recall hearing him state comparatively recently, and with great earnestness, that the results he had achieved were, in kind, the results that he had wished always to achieve; that (in effect) he asked no more than to be able, by dint of personal weight and by striking a note appropriate to his day and period, to accentuate some wholesome and immediately viable and vital tendency in the thinking world.

For this service at least, and because in his devotion to this mission he brought to so many doubting minds a fuller sense of freedom, Dr. James should be honored by physicians and claimed as a colleague of first rank.

The physician's work is primarily among individuals needing help. And among such individuals in the intellectual world, many of them stunted and unknown, Dr. James moved about like a torch-bearer, calling to one and another, "If you have anything to say on which you are willing to stake yourself, follow me and I will help you to be heard."

James J. Putnam, M.D.

Correspondence.

TREATMENT OF COMPOUND FRACTURES IN THE SOCIETY ISLANDS.

Boston, Aug. 23, 1910.

Mr. Editor: The medical historian should be a general reader for he will glean much valuable information which is not to be found in the ordinary paths of medical historical research. Having read this summer that most interesting work entitled "A Voyage to the Pacific Ocean; for Making Discoveries in the Northern Hemisphere," by Capt. James Cook, F.R.S., and Capt. James King, LL.D. and F.R.S., four volumes, New York, 1796, I came upon the following rather remarkable description of the treatment of compound fractures by the indigenous physicians of the Society Islands. This voyage was undertaken by Captains Cook, Gore and Clerke in the years 1776 to 1780; consequently this method of treatment was practised by the savages at least one hundred and fifty years or more ago.

In Volume II, Book III, "*On Occurrences at Otaheite and the Society Isles*," Chapter IX, describing the customs and habits of the natives, is to be found the following paragraph:

"In the arts, they are extremely deficient; yet they pretend to perform cures in surgery which our knowledge in that branch has not enabled us to imitate. Simple fractures are bound up with splints, *but if a part of the bone be lost, they insert between the fractured ends a piece of wood made hollow, to supply its place. The "rapaoo," or surgeon, inspects the wound in about five or six days, when he finds that the wood is partly covered by the growing flesh; and, in as many more days, visits the patient a second time, when it is generally completedly covered; and, when he [the patient] has acquired some strength, he bathes in the water and is restored.*"

The italics are mine.

Very truly yours,

Charles Greene Cumston, M.D.

REQUEST FOR POLIOMYELITIS MATERIAL.

The Rockefeller Institute for Medical Research.

New York, Aug. 24, 1910.

Mr. Editor: I would be greatly indebted to you for any assistance that you could render me through the columns of your journal in enabling us to secure specimens of the nervous system from fatal cases of epidemic poliomyelitis, a disease which is widely prevalent throughout the United States and Canada at the present time. We should like to obtain portions of the spinal cord and, by preference, of the lumbar or cervical enlargement, removed as soon after death as possible, and preserved in plenty of pure glycerine, either Squibb's or Merck's or Kahlbaum's, which specimens are to be used for experimental purposes. The specimens can be sent by express at our expense, or by mail addressed to me at the Rockefeller Institute, 66th Street and Avenue A, New York City.

Yours very truly,

Simon Flexner, M.D.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE FOURTEEN DAYS ENDED AUG. 24, 1910.

PETTUS, W. J., assistant surgeon-general. Granted one month and fifteen days' leave of absence from Aug. 29, 1910.

COFER, L. E., assistant surgeon-general. Granted six days' leave of absence from Aug. 22, 1910.

MEAD, F. W., surgeon. Granted thirty days' leave of absence from Aug. 23, 1910.

WHITE, J. H., surgeon. Granted one month's leave of absence from Aug. 17, 1910.

WILLIAMS, L. L., surgeon. Granted seven days' leave of absence from Aug. 11, 1910, under paragraph 189, Service Regulations.

GUITERAS, G. M., surgeon. Leave of absence for four days from Aug. 9, 1910, amended to read three days from Aug. 9, 1910.

STIMPSON, W. G., surgeon. Leave of absence for twenty days from Aug. 11, 1910, amended to read six days from Aug. 11, 1910.

SPRAGUE, E. K., surgeon. Granted one month's leave of absence from Aug. 28, 1910.

WICKES, H. W., surgeon. Leave of absence for one month from July 15, 1910, amended to read twenty-four days from July 15, 1910.

ANDERSON, JOHN F., passed assistant surgeon. Granted one day's leave of absence, Aug. 20, 1910, under paragraph 189, Service Regulations.

FOX, CARROLL, passed assistant surgeon. Granted ten days' leave of absence en route to station.

MCCLINTIC, THOMAS B., passed assistant surgeon. Granted seven days' leave of absence from Aug. 15, 1910, under paragraph 191, Service Regulations.

GWYN, M. K., passed assistant surgeon. Granted ten days' leave of absence from Aug. 28, 1910.

FOSTER, A. D., passed assistant surgeon. Directed to proceed to New Orleans, La., and report to the medical officer in command for duty and assignment to quarters. Aug. 15, 1910.

LANZA, A. J., assistant surgeon. Granted seven days' leave of absence from Aug. 14, 1910.

MARSHALL, E. R., assistant surgeon. Granted twenty-one days' leave of absence from Sept. 14, 1910.

KRULISH, EMIL, assistant surgeon. Granted one month's leave of absence from Aug. 16, 1910.

DUFFY, BENEDICT J., assistant surgeon. Directed to report to the medical officer in command at Buffalo, N. Y., for duty. Aug. 12, 1910.

CLEAVES, F. H., acting assistant surgeon. Granted fourteen days' leave of absence from Aug. 7, 1910.

GLEASON, C. M., acting assistant surgeon. Granted fourteen days' leave of absence from Aug. 15, 1910.

MACCALLUM, CHARLES, acting assistant surgeon. Granted thirty days' leave of absence from Aug. 12, 1910.

SCHUSTER, B. L., acting assistant surgeon. Granted four days' leave of absence from Sept. 1, 1910.

WRIGHT, F. W., acting assistant surgeon. Granted twelve days' leave of absence from Sept. 1, 1910.

THURSTON, E. J., pharmacist. Granted two days' leave of absence from Aug. 15, 1910, under paragraph 210, Service Regulations.

HERTY, F. J., pharmacist. Granted five days' leave of absence from Aug. 16, 1910, under paragraph 210, Service Regulations.

RYDER, L. W., pharmacist. Granted one day's leave of absence, Aug. 20, 1910, under paragraph 210, Service Regulations.

APPOINTMENT.

DR. BENEDICT J. DUFFY commissioned (recess) an Assistant Surgeon in the Public Health and Marine-Hospital Service, Aug. 5, 1910.

PROMOTION.

WICKES, HENRY W., passed assistant surgeon. Commissioned a surgeon (recess), to rank as such from Aug. 3, 1910.

BOARD CONVENED.

Board of medical officers convened to meet at the Marine Hospital, Memphis, Tenn., Aug. 22, 1910, to determine the fitness of Pharmacist C. R. Ott for promotion to the grade of Pharmacist of Class 2. Detail for the Board: Surgeon P. C. Kalloch, chairman; Acting Assistant Surgeon S. P. Brooks, recorder. Aug. 16, 1910.

RECENT DEATHS.

AMORY, ROBERT, M.D., M.M.S.S., retired, died in Nahant, Aug. 27, 1910, aged sixty-eight years.

CUMMINGS, IRVING OSCAR, M.D., M.M.S.S., died in Brewster, Aug. 2, 1910, aged forty-two years.

DR. JOSEPH J. HULL, of New York, retired, died on Aug. 26, in the seventy-seventh year of his age. Dr. Hull had been incapacitated for some years by ill-health, but formerly was a prominent practitioner and very highly esteemed.

Original Articles.

INDICATIONS FOR ABDOMINAL HYSTERECTOMY.

BY W. P. GRAVES, M.D., BOSTON.

In order to illustrate the various indications for the operation of abdominal hysterectomy, I have selected from my hospital and private practice a consecutive series of one hundred cases, which represent fairly well most of the conditions which require this operation. A discussion of this subject is not out of place on account of the very considerable difference of opinion that exists among surgeons regarding the advisability of hysterectomy in certain pelvic conditions. It affords also an opportunity for an expression of opinion regarding the comparative merits of the abdominal and vaginal route.

A classification of the cases arranged according to pathological conditions follows:

Pelvic inflammation,	35
Fibroids,	35
Cancer of uterus,	12
Ovarian disease,	10
Dysmenorrhea and neurasthenia,	3
Septic uterus,	2
Tuberculosis,	1
Atresia of cervix,	1
Menorrhagia at menopause,	1

GENERAL CONSIDERATIONS.

In deciding on the advisability of any given operation, it is always necessary to consider both the danger of the operation itself and the complications which may possibly ensue. The danger to life in the average operation of hysterectomy is not a particularly serious one, as is shown by the fact that in this series of one hundred cases there was only one death, which occurred in a case operated on for septic uterus, the patient having at the time of the operation an extensive peritonitis which would have proved fatal without operation. Shock and hemorrhage should occur only in operations of great gravity, as, for example, in advanced cancer or in conditions of very extensive adhesions. Only four of the cases in this series required stimulation for shock either during or after operation; one of these was an advanced cancer of the cervix in an old woman; one was a case of an enormous cystic fibroid occupying the entire abdomen with extensive adhesions; one was a case of an adherent primary carcinoma of the ovary, and one was a case of extensive pelvic inflammatory disease.

The accidents which may happen, aside from hemorrhage and shock, are represented by the following: In two cases one of the ureters was cut. One of these cases was the large cystic fibroid mentioned above and the accident was unavoidable. About three inches of the ureter was removed, the proximal end being tied above the brim of the pelvis. The patient had suppression of urine for thirty-six hours, but made a complete recovery without further symptoms. In the other case, a large fibroid, the ureter had been drawn out of position by the growth well up on the side of the fibroid; the ureter was included in the clamp on the uterine artery and cut, an accident which should have been avoided. An end-to-end anastomosis was performed, and the patient made an excellent recovery excepting for a temporary cystitis. In two cases of cancer of the cervix where the disease had infiltrated the bladder wall, the bladder was opened and partially resected; both cases resulted in a vesico-vaginal fistula, one of which healed spontaneously; the accident in these two cases was unavoidable. In one case of a large fibroid the bladder which was adherent to the anterior portion of the fibroid was accidentally opened; the rent was repaired and the patient made an uneventful recovery excepting for a temporary cystitis; the accident in this case should have been avoided.

The complications which may follow hysterectomy are represented by the following. Three cases had an infiltration of blood in the broad ligament, which caused some discomfort for several weeks following the operation. This complication is due either to a careless tying of the uterine and cervical vessels or to an extensive bleeding surface between the leaves of the broad ligament so that it is necessary to close the peritoneum over an oozing dead space. One patient developed an abscess in the broad ligament following operation for purulent pelvic inflammatory disease. The abscess was opened by a vaginal puncture and the patient recovered. Vesico-vaginal fistula occurred in two of the cancer cases, one of them healing spontaneously. Cystitis occurred in the two fibroid cases mentioned above, namely, one where a cut ureter was anastomosed and one where the bladder was wounded. One patient had pleurisy from which she recovered, and three cases had stitch abscesses, two of them being cancer of the cervix cases.

ACCIDENTS DURING THE OPERATION.

Operative shock,	4
Cut ureter,	2
Wound of bladder,	3

COMPLICATIONS FOLLOWING OPERATION.

Blood infiltration of broad ligament,	3
Abscess of broad ligament,	1
Vesico-vaginal fistula,	2
Cystitis,	2
Pleurisy,	1
Wound sepsis,	3
Deaths,	1

With regard to the question of the comparative merits of the abdominal and vaginal route, I am unqualifiedly in favor of the abdominal route for practically all cases. The cases in which shock and injury to the bladder and ureters took place could not have been performed by the vaginal route, and, with the exception of the three cases of stitch abscess in the abdominal wound, the convalescence of the other cases, where vaginal hysterectomy may have been possible, could not have been improved by a vaginal operation. The comparative merits of the vaginal and abdominal route in cancer cases will be discussed later. In cases of fibroids of the uterus it is desirable, when-

ever possible, to perform a supravaginal hysterectomy, which is a much less dangerous operation than a complete hysterectomy and one by which the pelvis can be left in a much more nearly normal condition by suturing the stumps of the round ligaments to the stump of the cervix and then covering over with peritoneum. The pelvis is left in a very natural anatomical relationship and absolutely prevents any possible future prolapse of the cervix and vagina, a complication which is extremely likely to occur after a hysterectomy if the pelvic floor is not supported in some such way. All these advantages are more or less lost by operating by the vaginal route. Vaginal hysterectomy for extensive pelvic inflammatory disease is for the most part not to be considered. The only cases in the entire series where I consider that the vaginal route might have been preferable were the two cases of septic uterus.

CHRONIC PELVIC INFLAMMATION.

The question between a supravaginal hysterectomy and a conservative operation in cases of pelvic inflammatory disease is one of importance on account of the great difference that exists in the ultimate condition of health following the two operations. It may be said at the outset that supravaginal hysterectomy for chronic inflammatory disease is almost always followed by an early and complete cure of symptoms and is one of the most satisfactory in its results of gynecological operations. Conservative surgery in chronic pelvic inflammatory disease, on the other hand, is one of the most unsatisfactory of pelvic operations, for although a certain percentage of even the most severe cases thus treated get well, nevertheless a very considerable number begin again, after a few months of relief of pain, to have pelvic distress, and continue for years in a state of chronic invalidism unless cured by the radical operation. It is not uncommon to see women who have undergone two or even three conservative operations that consisted of resections and releasing of adhesions still suffering vague pelvic discomfort with all the severe nervous symptoms which invariably accompany this disease. It is not the scope of this paper to investigate the pathology underlying the recurrence of symptoms following the conservative operation. In fact, the pathology is not perfectly clear, for although in the majority of cases adhesions reform with corresponding misplacement and immobilization of the organs, nevertheless I have on several occasions found the pelvis completely free from adhesions and the organs remaining from a previous operation in perfect position and yet have effected a complete cure of distressing symptoms by hysterectomy. It can only be said that the damage once done by gonorrheal infection to the pelvic organs is not easily repaired by a breaking up of adhesions and a removal of portions of the organs, but that the injury is often so deeply seated in the tissue of the organs that a symptomatic cure can only be effected by extirpation.

Nevertheless many cases of chronic pelvic inflammatory disease present themselves where the radical operation is out of the question, and where the surgeon must make the best of conservatism. Such cases comprise unmarried girls, young women about to be married or recently married, women whose chief complaint is sterility and women who either themselves or whose husbands object from sentimental reasons to the complete removal of the pelvic organs. The question of childbearing is the one on which the decision usually hinges. As a matter of fact, the woman whose pelvic organs have been even mildly infected with gonorrhea is in most cases doomed to sterility, yet pregnancies have followed reparative operations where the tubes have been completely occluded, and in cases like the above it is the surgeon's duty to improve every chance to restore to a sterile woman her lost function.

In making a decision as to the best procedure in a case of chronic inflammatory disease, I usually adopt the following rules:

1. In young women married or single the first operation should always be conservative unless the disease is so far advanced as to have destroyed both ovaries, in which case a removal of all the organs is indicated.

2. In young women where the conservative operation has been given a full trial without success, and the patient's usefulness is greatly impaired by her condition, hysterectomy is indicated.

3. In middle-aged women who have healthy children, hysterectomy is indicated unless the disease is slight or unless the patient is desirous of having more children.

4. In women beyond the childbearing age hysterectomy is always indicated.

The operation. — Supravaginal hysterectomy for pelvic inflammatory disease, though in many cases a difficult one to perform, is usually followed by a surprisingly good convalescence, apparently due to the immunity which the pelvic peritoneum has gained from its long combat with infection. The difficulty of the operation lies in the release of the pelvic adhesions. Facility in breaking up these adhesions is, however, soon acquired, if it be remembered that it can most easily be done by starting at the bottom of the plevis and working upwards, great care and patience being necessary when the intestines or bladder are involved. I have not yet found it necessary to resort to Kelley's method of bisection of the uterus.

Drainage is not usually necessary, but should always be employed if there is any doubt. Drainage, if used, should in most cases be through the posterior wall of the vagina.

ACUTE PELVIC INFLAMMATION.

Cases of acute salpingitis in the first attack, which demand immediate operation, do not as a rule require hysterectomy, as in most cases the ovaries are not damaged. These cases with proper drainage after a conservative operation often clear up with surprisingly few adhesions and make complete cures, though many do not. In the case of a chronic salpingitis with acute exacerbation the patient can in most cases be

kept in bed under local treatment until the process subsides, when the operation can be safely performed, and the method of operating carried out according to the rules laid down for chronic inflammatory disease.

FIBROIDS.

In cases of large or bleeding fibroids the indication for hysterectomy is perfectly obvious. In cases of small symptom-giving fibroids in childbearing women the indication for myomectomy is equally obvious if the fibroids can be easily enucleated. It should, however, be remembered that an extensive myomectomy is a more dangerous operation than a supravaginal hysterectomy and that any considerable mutilation of the uterus is inadvisable. The treatment of small or medium-size symptom-giving fibroids discovered at an age near or after the menopause is a matter involving considerable difference of opinion among practitioners. The old idea that fibroids atrophy after the menopause is still quite prevalent, and is largely the basis of the difference in opinion with regard to surgical treatment. Personally I have never observed the diminution or disappearance of a fibroid after the menopause, and I am inclined to ascribe many of the statements of such a process to faulty observation; on the other hand, it is a common experience to see fibroids increase after menopause. The possibility of a fibroid becoming sarcomatous later in life is something always to be borne in mind, although this pathological change is a rare one. It is much commoner to find an adenocarcinoma developing in the endometrium where the uterine fibroids are of long standing. These carcinomata are of a malignant nature, and recent observation shows that this condition occurs much more frequently than was formerly supposed. Of the thirty-five cases of fibroids represented in this paper, three harbored a well-developed adenocarcinoma in the uterine canal. There are numerous other forms of degeneration of a more or less dangerous nature, which it is not within the scope of this paper to discuss. The most important factor to consider, however, is the prolonged and exhausting menopause which even small fibroids may produce, with the resultant anemia, nervous exhaustion, etc. My rule is to perform supravaginal hysterectomy in all cases of fibroids which cause symptoms near or after the menopause or which show signs of development. In the case of small fibroids which do not give symptoms, operation is not necessary provided the patient presents herself for examination two or three times each year. Most fibroids may be removed by a supravaginal amputation, which is easier to perform and considerably less dangerous than the complete operation, which involves the removal of the cervix. In all cases the stumps of the round ligaments should be attached to the cervical stump in order to prevent a future prolapse of the cervix and vagina, which is a distressing complication and one which may easily occur even in women who have not borne children. A glance at the table of complications shows that there is little danger to the operation excepting in the severest cases.

CANCER OF THE UTERUS.

Squamous-cell carcinoma of the cervix and adenocarcinoma of the body of the uterus are two such widely different diseases that it is necessary to consider them under two headings. The difference in the two forms of uterine cancer is only one of the many manifestations that show that the cervix and body, though ostensibly belonging to the same organ, nevertheless are histologically, pathologically and physiologically two distinct organs.

Carcinoma of cervix. — In the treatment of this disease more than in any other does the debate between the supporters of the vaginal and abdominal routes deserve consideration. Excellent results by the greatest exponents of these two methods, namely, Schauta and Wertheim, are frequently presented. The claims for the two methods may be briefly summarized thus. Wertheim urges that by the abdominal route a greater field for operation is secured. Infected glands along the iliac veins may be dissected out, a greater percentage of operability is possible and a higher percentage of cures can be demonstrated. Schauta, on the other hand, claims for the vaginal route a smaller operative mortality and less danger to the urinary tract, stating also that cases which cannot be reached by the vaginal route are inoperable by any method. Wertheim's statistics, which are models of painstaking accuracy and fairness, are most convincing.

The question of the percentage of operability in cases of cancer of the cervix presenting themselves for treatment is one that is dependent largely on the skill and experience of the surgeon. Wertheim has within the last ten years increased his percentage of operability enormously, while decreasing his primary mortality and increasing at the same time the percentage of permanent cures. These figures can only be explained by a very great increase in operative skill in the performance of a large number of operations. So long as surgical intervention is the only possible available cure for cancer, the example of work like Wertheim's is a most inspiring one. In general, the question of attacking cancer of the cervix by a radical operation is the same as that when referred to cancer in any other part of the body. I believe it is the surgeon's duty to undertake a radical cure, where there is a possible chance of extirpating the disease, bearing in mind that not infrequently cases of hopeless appearance either get well or have long periods of health and comfort before recurrence. The authentic instances of a spontaneous cure of cancerous tissue left behind from an incomplete operation are also a matter of encouragement in the more desperate cases.

The operability in cases of cancer of the cervix has been enormously increased for the general surgeon by Wertheim's work. He has demonstrated the possibility of removing a large amount of parametrial and paravaginal tissue with little

danger to the ureters and with perfect control of the formerly troublesome vaginal plexus of veins.

In deciding the operability of a given case, one usually considers the amount of invasion by the disease of the vagina, the bladder and the broad ligaments. If the vaginal wall is invaded, and there is some mobility of the uterus, the surgeon must decide the question of operation by his individual ability and skill in removing the vagina. If the bladder is involved and there is mobility of the uterus, it may be remembered that considerable portions of the bladder may be resected without serious results. If the broad ligaments are invaded, the mobility of the uterus is diminished. The amount of mobility of the uterus constitutes, therefore, the chief factor in making the decision as to operation. Before relegating a case with an immobile uterus to the list of inoperability it should be remembered that a large evertent growth from the portio vaginalis may mechanically cause immobility of the uterus, and that when the mass is curetted away the uterus is in reality sufficiently movable to indicate operation. In some cases, also, the thickening of the parametrium may be due to an old pelvic inflammation or an inflammatory reaction from the cancer itself. A decision as to the operation should, therefore, not be made until the excrescent growth in the cervix has been curetted. If there is still doubt as to the operability it is fairest to the patient to open the abdomen and make the final decision by intra-abdominal inspection and palpation. The presence of glands along the iliac vessels does not necessarily contra-indicate operation. Although this complication makes the prognosis of recurrence much less favorable, yet a permanent cure is possible even under these conditions, as is shown by Wertheim's figures.

The operation.—Sufficient time has not elapsed since the cases which are included in this series, and those which have been done since, to make any accurate statement with regard to ultimate cure, in accordance with the formula which Wertheim has laid down. It can be said, however, that, so far as I have followed the cases, the results have been, for the most part, very satisfactory and the operations well worth while. Two of the cases developed vesicovaginal fistulas, one of them healing spontaneously. There were no deaths in the series presented in this paper. This, however, is somewhat a matter of chance, as, of course, in advanced cases the operation is an extremely dangerous one and at best must be attended by a fairly large mortality. In the list of cases which I have operated on since the completion of the series reported in this article, I have had two deaths from operative shock, bringing the mortality in the neighborhood of 11%. I am indebted to Dr. H. T. Hutchins for the technical details of the Wertheim operation.

CANCER OF THE BODY OF THE UTERUS.

Adenocarcinoma of the body of the uterus, being one of the less malignant forms of cancer, offers an excellent opportunity for cure by hysterectomy unless extremely advanced. The diagnosis should always be made by microscope. The best operation is a complete hysterectomy by the Wertheim method, although it need be less extensive as there is usually no involvement of the vagina and rarely any extension into the parametrium. The operation is a comparatively safe one and should be attended by no serious complications. The prognosis as regards recurrence is excellent. The disease usually gives early warning of its presence by bleeding, so that in most cases patients come for operation before it is too late. The possibility of the occurrence of cancer of the body of the uterus should always be borne in mind in patients who bleed after the menopause. In this case the microscopical examination of curettings from the endometrium should always be made. It should be remembered that in the early stages the disease may be localized in a comparatively small area of the uterine canal, so that it is necessary to anesthetize the patient in order to perform a very thorough curetting, bearing in mind the fact that the starting point of the cancer is usually near one of the cornua. It is important, too, that the pathologist should examine *all* the curettings in a suspected case before making a negative diagnosis. When the disease is fairly obvious and the uterus is soft and pulpy the curettings for examination may sometimes be removed without ether.

OVARIAN DISEASE.

The question of performing hysterectomy in case of ovarian disease is sometimes one of much importance and one on which surgeons do not uniformly agree. I usually govern my decision in a given case by the rule that *whenever it is necessary to remove both ovaries, it is best also to remove the uterus.* Comparative observations of the later health of cases where this rule has been carried out, and where it has not, has convinced me beyond all doubt that when feasible the rule is to be recommended. The uterus minus the ovaries is a useless organ, and it would not be difficult to show from records that the presence of such a uterus is commonly the cause of more or less serious trouble. It is rare that a supravaginal hysterectomy adds greatly to the severity of an ovarian operation. In fact, it is usually the case in extensive double ovarian disease that the operation is much facilitated by the removal en masse of all the pelvic organs. These remarks apply to cases of extensive pelvic inflammatory disease and extensive pelvic tubercular disease, bilateral ovarian tumors whether malignant or not, and ordinary castration.

There still remains a series of cases where the decision may be of extreme importance, namely, in cases of unilateral ovarian tumors, the question being whether to remove the other ovary and, consequently, in accordance with the rule, the uterus also. In deciding this question, the knowledge of pelvic pathology is of great value to the surgeon.

When malignant disease occurs in one ovary,

I am accustomed always to remove the uterus and other ovary. The reason for this is that all ovarian tumors, especially the malignant forms, have a tendency to be bilateral, and that the development of the disease in the two ovaries may not by any means be contemporary. There is a case in the present series of a carcinomatous cyst of the ovary which developed thirteen years after the removal, by Dr. Davenport, of a carcinomatous cyst of the other ovary.

The rule of removal of all the pelvic organs in the case of unilateral ovarian cancer is a simple one if the malignant disease is perfectly obvious. It is not, however, always easy to tell by casual inspection whether or not an ovarian cyst is malignant. One may, however, be assisted by remembering a few pathological facts. Retention cysts of the ovary only very rarely become malignant and may be removed without disturbing the other pelvic organs excepting possibly by a partial resection of the other ovary in case it shows a tendency to cystic degeneration. The multilocular pseudo-mucinous cysts do not have a special tendency to become malignant, and may often be removed without disturbing the other organs in case the other ovary is normal. The serous cyst-adenomata, on the other hand, not only have a greater tendency to malignancy than does the pseudo-mucinous type, but they are also more apt to develop bilaterally. This latter fact is especially true when the cysts have apparently developed as a result of a chronic pelvic inflammation.

New growth cysts in middle-aged or elderly women are more apt to become carcinomatous than in younger women, and when they do become so the process is usually more malignant.

As a rule, the carcinomatous process starts on the inside of the serous cyst-adenoma, and a cyst which on the outside has an entirely innocent appearance may contain most dangerous contents, the spilling of a few drops of which in the abdominal cavity may lead to a rapid and malignant growth of seed cancers throughout the peritoneum. One of the cases in the series illustrates this fact. A very large serous cyst-adenoma was removed from a patient of middle age. Extensive adhesions made the operation so difficult that it became necessary to evacuate the cyst of its contents before the operation could proceed; although great care was used a few drops of the fluid leaked out around the trocar. The lining of the cyst appeared normal by gross inspection. Careful microscopical examination of the wall disclosed a beginning carcinomatous process. Several months after the operation there developed a most malignant carcinomatosis of the entire peritoneal cavity.

With these few pathological observations in mind, I am accustomed to adopt the following rules in making a decision as to the best operative procedure when the diagnosis of malignancy in a unilateral new growth ovarian tumor is not perfectly obvious.

1. In the case of new growth tumors of the ovary in middle-aged or elderly women, both ovaries and uterus should usually be removed, unless the tumor is obviously non-malignant.

2. When a unilateral serous cyst-adenoma has developed from a chronic inflammatory process, both ovaries and uterus should be removed.

In these cases the opposite adnexa are nearly always much damaged anyway so that a supravaginal hysterectomy with removal of both ovaries is usually clearly indicated according to the rules observed under the heading of chronic inflammation.

3. In the case of a woman in the childbearing age, when it is important to preserve the other ovary and uterus, unilateral retention cysts may always and unilateral multilocular pseudo-mucinous cysts may usually be removed without disturbing the other organs.

4. In the case of a unilateral serous cyst-adenoma, if it is non-adherent and the other ovary is normal, it may be removed without disturbing the other organs, if it can be shown in all probability to be non-malignant. It should, however, be removed *in toto* without spilling any of its contents no matter how large an incision is required. The trocar should be resorted to only when the mechanical difficulties of removing the entire cyst can be overcome in no other way. After the removal of the cyst it should be opened and the lining wall carefully inspected for cancerous excrescences.

DYSMENORRHEA AND NEURASTHENIA.

Patients occasionally present themselves who suffer such extreme dysmenorrhea that they do not recover between the periods. Nervous and mental symptoms ensue of such a character as to render the patient's life practically useless. All palliative treatment and repeated palliative operations are of no avail and serve only to discourage the patient still more. When every effort to relieve the patient has failed, castration is the only procedure left. In these cases I prefer a supravaginal hysterectomy rather than a removal of the two ovaries, experience having shown that the patient makes a better convalescence and is ultimately more comfortable than if carrying the uterus minus the ovaries. The results in the three cases reported in this series were very satisfactory.

SEPTIC UTERUS.

The indication of hysterectomy for a septic uterus is an extremely rare one, and should be resorted to only in extraordinary cases. One of the two cases recorded in this series was in this class. The patient had had an instrumental abortion performed, and carried a septic fetus and placenta for over a week; cleaning out the uterus did not affect a gradually rising temperature, pulse, and leucocytosis. There was no peritonitis and the sepsis seemed to be confined entirely to the uterus, which was very foul. As the patient was getting rapidly worse, a complete hysterectomy was performed followed by an excellent recovery. Microscopical examination showed the entire myometrium to be packed with pus cells.

The second case was a similar one, excepting that the patient had a peritonitis extending to the umbilicus. The idea of operation was prompted by the success of the case just cited. The patient was not helped and died. The operation in this case was probably ill-advised, though the patient would undoubtedly have died anyway. This was the only death in the series here reported.

COMPLETE PROCIDENTIA.

Of seventy-five cases that I have operated on for a complete procidentia, I have found only one which required a hysterectomy. As a rule, procidentia cases present an enormous hypertrophy of the cervix and with it an atrophy of the fundus; the greater bulk of the uterus is, therefore, included in the cervix. By performing a very high amputation of the cervix, the uterus is thus relieved of its weight, and the atrophied fundus may be made use of as a firm cap to the vagina, and may be employed as an excellent medium by which the vagina can be attached to the abdominal wall (modified vaginapexy). It may, however, happen that the uterus requires removal for some other cause, e. g., fibroids, carcinoma, or chronic congestion with enlargement of the fundus. The case recorded in this series was of the last-named type. In case there is a greatly hypertrophied cervix in addition to a large heavy fundus, it is easiest to perform a so-called combined hysterectomy. On account of the long attachment of the cervix to the bladder which would be difficult to separate from the abdominal side, the cervix is first stripped from the bladder and rectum by the vaginal route as far as the level of the uterine vessels. The patient is then placed in the Trendelenburg position, the uterine attachments tied and cut, and the uterus drawn through the vaginal introitus. The vagina is then attached to the abdominal wall by the so-called operation of abdominal colporrhaphy or vaginapexy.[1]

ATRESIA.

Cases of congenital and acquired atresia of the vagina may usually be cured by the various plastic devices which have been described by me elsewhere.[2] When, however, the atresia or stricture extends to or occurs in the cervix of a menstruating uterus, palliative measures fail, and it is impossible to keep the cervical canal patent by plugs, stem pessaries or any form of plastic surgery. It becomes necessary then to stop mentruation. This can be done either by removing the ovaries and leaving the uterus, or by removing the uterus and leaving the ovaries. The latter is the procedure to be recommended as the uterine contents are usually infected after the various attempts to keep the cervix patent. In removing the uterus, it is not necessary to do a complete hysterectomy, but the cervical mucous membrance should be removed by a cone-shaped incision because of the fact that the glands of the cervix are of the mucous type, and may continue to secrete a certain amount of mucus after the removal of the fundus.

EXCESSIVE FLOW AT THE MENOPAUSE.

The underlying cause of the prolonged exhausting menorrhagia which some women experience at the climacteric age has not yet been satisfactorily explained. The cause most commonly ascribed to it is a chronic gland hypertrophy of the endometrium. Although this condition is usually found in the microscopical examination of the curettings of such cases, nevertheless it is not always so. Some cases are benefited or cured by a curetting. It sometimes happens, however, that even repeated curettings have no effect whatever, and that after many months the patient becomes extremely anemic, and with associated neurasthenic symptoms often of a severe type. The various uterine drugs are practically useless. In a case of this kind when every possible effort in the way of palliative treatment has been made and found ineffectual, the indication is clearly operative. The best operation is a supravaginal hysterectomy with a removal of the ovaries. The alternative operation of removing a wedge from the fundus of the uterus, including the endometrium, has no advantages over hysterectomy either in simplicity or in lessened danger to the patient.

TUBERCULOSIS.

In many cases of tubercular salpingitis the process is found to be almost entirely localized in the tubes, in which case a double salpingectomy is all that is necessary, the prognosis as to further extension in the pelvic peritoneum being extremely good. Extensive tuberculosis of the pelvis, on the other hand, is a serious and difficult condition to treat surgically on account of the tremendous formation of adhesions, and the tendency of these adhesions to bleed on being separated. The indication in this case is a painstaking release of all the pelvic organs from adhesions, followed by a complete hysterectomy and drainage through the vagina.

TWENTY-ONE CASES OF ACUTE PANCREATITIS.

BY F. G. BALCH, M.D.,
Visiting Surgeon, Massachusetts General and Faulkner Hospitals;
AND
G. G. SMITH, M.D.,
Assistant in Anatomy, Harvard Medical School.

ACUTE pancreatitis was comprehensively described for the first time in 1889, when Fitz, in the Middleton-Goldsmith Lecture before the New York Pathological Society, classified all cases as either hemorrhagic, gangrenous, or suppurative. Since that time, the work of almost every investigator in this field has been based upon this classification. Mayo Robson, however, describes parenchymatous pancreatitis (as distinct from catarrhal pancreatitis) as acute, subacute or chronic. Under the head of acute pancreatitis he places the hemorrhagic type, divided into ul-

tra-acute and acute, the gangrenous type and the diffusely suppurative type. Abscess of the pancreas, which he places in a subacute class, was, nevertheless, found in one of our cases (Case 20) one day after the onset of the symptoms. He distinguishes between the ultra-acute hemorrhagic type, in which hemorrhage precedes inflammation, and the acute hemorrhagic type, in which the order is reversed. This seems a very subtle distinction, one which is rather difficult to make on the operating table. He found two cases, however, which presented the picture of pure hemorrhage and which perhaps justified the subdivision of acute hemorrhagic pancreatitis which he made.

Pathological findings show the leading lesion of all acute pancreatitis to be hemorrhage, gangrene or suppuration. We have looked up all cases proved by autopsy or operation to belong to one of these classes which have occurred at the Massachusetts General Hospital since 1889, and at the Faulkner Hospital since 1902. Twenty one in all, 18 from the Massachusetts, 3 from the Faulkner, were collected. Of these 21 cases, 16 were hemorrhagic, 3 gangrenous, 1 suppurative, and there was 1 case (Case 21) which in the course of two operations showed characteristics of all three types. Eleven cases were men, 11 women. The ages were

	Cases.
From 20 to 30 years,	3
From 30 to 40 years,	5
From 40 to 50 years,	7
From 50 to 60 years,	4
60 years,	1
70 years,	1

Gangrenous pancreatitis is a late development of the hemorrhagic disease. Since the three gangrenous cases and Case 22 began with the hemorrhagic form, and since sixteen of the twenty-one cases were hemorrhagic when seen, it is fair to say that the great majority of all acute diseases of the pancreas begin with hemorrhagic inflammation. Experimental work has shown that a pressure of only a few centimeters of mercury is enough not only to dam the pancreatic secretion, but to force it back through the ducts from which it came. When thus pent in, the pancreatic juice and whatever fluid or infection is mixed with it either digests through or ruptures the walls of the minute ducts and spreads throughout the parenchyma. Once within the tissues, the pancreatic secretion causes their necrosis and corrodes the walls of the blood vessels. Infection, usually by the bacillus coli communis or staphylococcus, which exists in the stagnant secretion, causes an exudate to be formed in the interstitial tissue. From these factors, we get the pathological condition known as acute hemorrhagic inflammation of the pancreas. The process may involve the gland entirely or only in part. In the early stage the affected portion is enlarged, hard and of deep red color. In one case (Case 11) blood was seen oozing from the surface of the pancreas. Somewhat later, the very acute engorgement subsides; the gland is still enlarged, but not so hyperemic. On section, the tissue is streaked or mottled with red, or may be so full of extravasated blood as to present a uniformly reddish surface. Frequently small areas of cloudy, grayish, necrotic-looking tissues are seen, and these may continue to soften until they contain a purulent or blood-stained fluid. Microscopic examination shows blood extravasated between the lobules, a cellular and fibrino-cellular exudate in the interstitial tissue, and "the fat cells empty or appearing as a fibrinated mesh-work of fine granular material, bacteria and acicular fat crystals." (Fitz.)

In almost every case of hemorrhagic pancreatitis the fat about the pancreas is studded with areas of fat necrosis. These spots, first connected with pancreatitis by Balser in 1882, are only a few millimeters in diameter and are due to the alteration of the fat by the escaped pancreatic juice into fatty acids and glycerine. They are white, not elevated, and under the microscope are seen to consist of acicular crystals of fatty acids. It is probable, as has been suggested, that the fat-splitting ferment is conveyed to them through the lymphatics, for in one of our cases (Case 2) they were found on the upper surface of the diaphragm and in the mediastinum, and in another case (Case 13) they occurred in the subpleural fat as high as the top of the pleural cavity.

Hemorrhagic pancreatitis has been attributed to various causes. Fitz thought that people with gastric or gastro-duodenal indigestion were most liable. In only two of the cases we collected was previous digestive trouble mentioned. Opie and Robson regard pathological conditions in the bile ducts a probable etiological factor. A number of experiments along this line have been carried out, perhaps the most final of which are those of Flexner. He found that bile salts were a possible cause of hemorrhagic pancreatitis, and that the fresher the bile, the more acute their effect. If, on the other hand, the bile was altered by the admixture of colloid material such as is yielded by catarrh of the biliary passages, it caused in the pancreas a much more chronic change. A possible method by which bile might cause acute pancreatitis is illustrated by a case of Halsted's quoted by Opie. A small biliary calculus was found in the orifice of the ampulla of Vater, completely blocking the exit of bile, yet not large enough to prevent bile from passing from the common duct into the duct of Wirsung. In one of our cases (Case 12), a similar condition, in which the mucosa of the pancreatic duct was coated with greenish-tinged mucus, was discovered. In another (Case 13) the orifice of the ampulla was occluded by a tenacious plug of mucus. In a third case (Case 1) the common duct was dilated to the size of the little finger, and in the duodenum, apparently just passed, lay a gallstone the size of a hickory nut. As Opie has pointed out, however, the exact anatomical conditions under which a gallstone may convert the common duct and the pancreatic duct into a continuous channel occurs in but "a small proportion of cases."

It is possible, as has been suggested, that edema about the papilla may cause the bile to enter the

duct of Wirsung, or perhaps the orifice of the ampulla, dilated by the passage of the gallstone, admits the duodenal contents into the pancreatic duct. Certainly there is some relation between acute pancreatitis and gallstones. Opie collected a series of 41 cases associated with them. Deaver, in 6 cases of acute pancreatitis, found gallstones in 4. In our 17 cases of hemorrhagic pancreatitis, 6 had gallstones, 2 had thickened gall bladders, and in another the gall bladder could not be emptied by pressure and upon opening it a very dark, viscid bile was found. In 4 cases the condition of the bile passages was not mentioned. Thus 9 in 17 cases showed some evidence of biliary disease. Seven of these 9 cases gave a history of some kind of epigastric or right upper quadrant pain for months or years before their present illness. In another case the past history could not be obtained. The ninth case had had no pain previously. Of two of the cases with normal gall bladders, one had had epigastric pain without jaundice four or five times in as many months; the other had had occasional pain in the right hypochondrium for seven years.

Another possible cause of hemorrhagic pancreatitis, as shown by the experiments of Hlava, may be the entrance of hyperacid gastric juice into the pancreatic duct. A 0.1% solution of hydrochloric acid injected into the pancreatic duct of cats caused a hemorrhagic pancreatitis fatal in three days. The same result has been caused by the injection of fatty acids, of bacterial cultures and other solutions. In some cases, the ligation of the duct of Wirsung alone induced the disease.

Obesity and arteriosclerosis have been thought to predispose to this disease. In our 21 cases, obesity was mentioned in 5, arteriosclerosis in 3.

The general conclusion to be drawn from the foregoing data is that hemorrhagic pancreatitis is an acute disease of the pancreas which is almost always superimposed upon a chronic disorder of the stomach, duodenum or biliary tract.

In almost every account of the symptoms of acute pancreatitis, the description by Fitz is quoted verbatim. This is because no one can improve upon it in brevity, clearness or accuracy; we claim no more originality than the rest. The attack, Fitz writes, "begins with intense pain, especially in the upper abdomen, soon followed by vomiting, which is likely to be more or less obstinate, and not infrequently by slight epigastric swelling and tenderness with obstinate constipation. Normal or subnormal temperature may be present, and symptoms of collapse precede by a few hours death, which is likely to occur between the second and the fourth day."

To this picture the majority of cases of acute pancreatitis are true. In 17 of the 20 cases of hemorrhagic and gangrenous pancreatitis which we have collected, the manner of onset was described. In 13 it consisted of a sudden, griping pain in the epigastrium; in 4, it began more gradually. Upon admission to the hospital, of the 14 patients whose pain and tenderness were located more definitely than in "upper abdomen," 4 had their greatest suffering in the epigastrium alone, 1 in right hypochondrium alone, 6 in epigastrium and right hypochondrium, 1 in epigastrium and right iliac region, 1 in epigastrium and left hypochondrium, and 1, with a tumor across entire upper abdomen, complained of pain only in the left iliac region. In the 17 cases of hemorrhagic pancreatitis were noted vomiting in 11, distention in 7 and cyanosis in 4. Seven at entrance had a temperature of 100° or less; 3 between 100° and 101°, 4 above 101°. One (Case 9) had a temperature of 106.°5. The pulse-rates ranged from 70 to 140, only 3 being above 120. In 10 cases white counts varying from 7,400 to 38,000 were made. Although this series of 10 cases is far too small to allow of any generalizations, it is of interest that of the 5 cases with a leucocytosis of 20,000 or more, 4 showed abnormalities of the gall bladder. (The 3 other cases with biliary disease had no white count recorded.) Three of the acute hemorrhagic cases presented a tumor in the upper abdomen, in every case in the right hypochondrium; 3 others had slight jaundice, as evidenced by conjunctiva or by urine. Sugar was present in the urine of 3 while in the hospital.

In most of these cases, collapse, frequently with cyanosis, preceded a fatal termination. Eleven cases were operated upon within three days after the beginning of their acute attack. Of these, 7 died in from one and one-half hours to four days after operation; one lived and did well for twelve days, then developed an abscess about the pancreas and died about four weeks after the first operation. Of the recoveries, one has been well for three years after operation; another is living, although he has as much as 7% of sugar in his urine, seven years after operation, and the third, two months after operation, is well. Of the 6 unoperated cases in our series, none lived over eleven days. In the Massachusetts General Hospital records for the past twenty-one years, there is only one case recorded as recovering without operation.

To give non-operative treatment its entire due, we must admit that Case 14 recovered from acute pancreatitis without surgical intervention to aid that organ. He was operated on and his appendix was removed; then, through the presence of fat necrosis, pancreatic disease was suspected, the organ was palpated and found "somewhat thickened." He was sewed up tight, and, in spite of delirium tremens, made a good recovery. For two and one-half years he was in the full enjoyment of health; during the past three months, however, a persistent cough and steady loss of weight, perhaps due to incipient tuberculosis, have not improved his condition. As there may have been recoveries without operation which were not recognized as being acute pancreatitis, our figures are not absolute proof of the value of operative treatment.

As regards the pathological conditions present at operation or at autopsy, there is marked uniformity. In 17 cases of the hemorrhagic type the presence or absence of free fluid was recorded in 13, and of these 13 cases, 12 had free fluid. Fourteen

cases are on record as showing more or less disseminated fat necrosis.

In the diagnosis of acute hemorrhagic pancreatitis, the chief diseases to be differentiated are intestinal obstruction following concealed hernia or intussusception, perforation of the gall bladder, stomach or duodenum, or of a high appendix. There are practically no other abdominal crises which have the terrific onset of acute hemorrhagic pancreatitis. Intestinal obstruction, indeed, seldom has an equal acuteness of onset followed immediately by collapse. In pancreatitis the bowels usually can be made to move by enemata. The perforation of a hollow viscus, although it may occur with remarkable suddenness and very severe pain, causes a temporary collapse from which the patient very soon recovers. The signs of peritonitis then gradually increase, with a secondary collapse as their accompaniment.

The picture of typical acute hemorrhagic pancreatitis, distinguished by an agonizing pain, without corresponding tenderness, in the epigastrium; by feeble, slow pulse, normal temperature and persistent vomiting, and by a visible prominence in the epigastrium, is distinct from that of any other abdominal condition. If there is an abnormal amount of fat in the stools, causing a layer of oil to float above them, or if the Cammidge reaction is present in the urine, the diagnosis may be regarded as established.

The Cammidge test, advocated by Cammidge and Robson in 1904, depends upon the presence in the urine of an abnormal amount of pentose. Pentose is a constituent of many organs, but is present in the pancreas to a much greater extent (2.48%) than in any other. (The organ next richest in pentose contains only .56%.) The disintegration of any tissue rich in nucleoglycoproteids yields pentose, but practical tests have shown, according to J. E. Schmidt, that pneumonia and acute appendicitis with peritonitis are the only other diseases in which the reaction is common.

Robson and Cammidge, in 6 cases of acute pancreatitis, found the test positive in every case. The consensus of opinion drawn from the criticisms of Schmidt, Kinnicutt, Speese and Goodman and Ochsner is that, whereas a positive test in itself is not absolutely diagnostic of pancreatitis, it is "strongly suggestive" or "corroborative" evidence of inflammation and disintegration of pancreatic tissue.

This position is seriously undermined, however, by the work of Boos and Harmer, at the Massachusetts General Hospital. In a communication published in the BOSTON MEDICAL AND SURGICAL JOURNAL for June 16, 1910, they report the result of their investigations with the Cammidge test on a variety of diseases. They performed the test forty-seven times, and in no case with a leucocytosis of 13,500 or over did they fail to get a positive result. In most of these cases there was no possibility of pancreatic disease.

As regards the treatment of hemorrhagic pancreatitis, most writers advise against operation during the very acute stage, while the patient is in collapse. Fitz's opinion in 1889 was that operation in any case except one with abscess formation was useless. Reports of successful operations upon the acute hemorrhagic type since then have forced a modification of this dictum, and recently we find Ochsner advocating as early operation as possible. Granted that operating when an abscess is found is most desirable, it is certain that comparatively few cases live, if not operated upon, until that stage. It is equally sure that a certain number of cases will recover when operated upon during the first few days of the attack. We have collected three such cases, and in the literature are now reported a fair number of them.

The object of operating is to supply free exit for pancreatic secretion, and also to drain the infected tissues as in any other forms of diffuse inflammation. Von Mikulicz advocated free incision into the brawny, hyperemic gland. This was done in a case which Robson reports, and by C. A. Porter in Case 8; again, a surgeon of Salisbury, England, excised the affected portion of the head of the pancreas two hours after the onset of the attack. (The patient died fifteen days later of diarrhea, the record states.)

Gangrenous pancreatitis, save in its pathology, differs little from the hemorrhagic type. It is a later development of that type, hence the symptoms at the onset are those of hemorrhagic pancreatitis. If the attack has been of more than two weeks' duration, the symptoms will probably have decreased in severity. It may, however, be well within the limits of an acute attack, as in two of our cases in which, after nine and eleven days respectively, the pancreas was found to be partically or entirely necrosed. The diagnosis cannot be made without opening the abdomen except in those rare cases in which a portion of the gland, sloughing into the bowel, has been passed by rectum. Of the four cases which we collected, one, after a history of three months' illness, recovered from an operation at which the pancreas was found to be "more or less necrotic." Her subsequent history we have been unable to obtain.

Suppurative pancreatitis presents a somewhat different picture. It may consist of small abscesses throughout the gland, of a single abscess of the tissue, or of an abscess filling the omental bursa. It may follow acute hemorrhagic pancreatitis, as in Case 21, in which a sloughing pancreas was found floating in pus, or, as in Case 20, may be only a single abscess appearing one day after the first symptom.

This type is manifested by epigastric pain of rather gradual onset, accompanied by local tenderness, perhaps tumor formation, vomiting and a slight temperature. In one of our cases the white count was 21,600; in the other, 26,000. In neither case did free fluid or fat necrosis exist, and this, Fitz says, is usual in suppurative pancreatitis.

Operation in this class may be undertaken with good hope of recovery. The sooner the operation, the less will the pancreas be impaired.

CONCLUSIONS.

From the literature and the cases which we have looked up, we draw the following conclusions.

Almost all the acute diseases of the pancreas begin as an acute hemorrhagic inflammation, accompanied usually by free fluid in the peritoneal cavity and by disseminated fat necrosis.

Operation is the treatment indicated, unless the patient is in such severe collapse that the additional shock would surely be fatal.

The object of operation is to drain the pancreatic secretion and the products of infection; this is best done by incising the tissue of the gland, as advised by Porter, and by carrying the drainage through the gastro-hepatic omentum, close above the lesser curvature of the stomach.

CASES.

Acute Hemorrhagic Pancreatitis.

CASE 1. June, 1889. F. L., aged sixty, male.

Past history. — For three months had a sharp pain in epigastrium coming on two hours after meals.

Present illness. — Entered Massachusetts General Hospital with vomiting, normal temperature and very severe pain in epigastrium and left hypochondrium. Deep pressure in epigastrium elicited slight tenderness. He failed rapidly and died within a few hours. Before death, cyanosis and a prominence in epigastrium were noted.

Autopsy showed a fat man, slightly jaundiced. Six or eight ounces of free fluid in abdomen. Fat necrosis present. Head of pancreas was opaque, reddish-gray in color, tail was a grayish-pink. Throughout gland were spots and streaks of an opaque white and patches of thickened interstitial tissue. No thrombi in large veins. Surrounding fat tissue was moderately infiltrated with blood. Gall bladder contained more than one hundred stones. The common duct was distended to size of little finger and in duodenum was a gallstone the size of a hazel nut.

Diagnosis. — Acute hemorrhagic pancreatitis; cholelithiasis.

CASE 2. September, 1894. J. H., aged fifty-two, female.

Past history. — "Stomach trouble" for five years.

Present illness. — Two days before entering Massachusetts General Hospital she had a severe cramp in upper abdomen, and vomited. For a short time she was relieved, but the pain returned and continued up to the time she entered the hospital. Examination showed a very fat woman, cyanotic and dull. The abdomen especially in the epigastrium was much distended, very tense, and fairly tender. Temperature was 101°, pulse 110, white count 18,000. She died in three days, without operation, with delirium and a failing pulse.

Autopsy showed blood-stained fluid and fat necrosis in peritoneal cavity. The necrosis extended even along the upper surface of the diaphragm into the mediastinum.

Duct of Wirsung appeared normal. Pancreas was twice normal size, firm, dry, of dark, blackish-red color, mottled by opaque yellowish-red patches. No normal structure could be seen. Splenic vein was partly thrombosed. The urine showed 6.1% sugar.

CASE 3. November, 1894. H., aged seventy, male, clerk.

Past history. — Good.

Present illness. — Three days before entrance into Massachusetts General Hospital he noticed dull pain extending from epigastrium to right iliac fossa. This had continued, but had not been extremely severe. He vomited at the onset and had vomited every day since; the day before entrance vomitus was stercoraceous and his bowels did not move.

Examination showed an old man in good condition. Abdomen not distended. In right upper quadrant was a mass, flat on percussion. He was not operated upon, but gradually grew feebler, dying eight days after entrance.

Autopsy showed hemorrhagic pancreatitis. (Further details could not be found.)

CASE 4. August, 1895. C., aged forty-seven, female, dressmaker.

Past history. — For fourteen years she had pain in epigastrium radiating to back and right side. The attacks would end in vomiting and at times were accompanied by slight jaundice.

Present illness. — During five months before entrance she had had eight such attacks, usually occurring two or three hours after eating. Examination showed a tumor the size of an orange below right costal margin. She entered the Massachusetts General Hospital.

Operation showed a thickened gall bladder and general fat necrosis. A hard mass with adherent intestines was felt in the epigastrium. The abdomen was sewed up tight and the patient died three days later. There was no autopsy.

CASE 5. October, 1896. J. O., aged forty, male.

Past history. — Frequent flatulence. Digestion otherwise good. Never jaundiced.

Present illness. — Four days before admission to Massachusetts General Hospital he was seized with pain in upper abdomen, vomiting and distention. He became steadily worse. Examination showed a well-nourished but cyanotic man; abdomen extremely distended, with tenderness in epigastrium and dullness in right flank. Temperature, 105°. Pulse, 140. He died three hours after entrance.

Autopsy showed 500 ccm. of dark brown, rather sticky fluid in abdomen. Posterior wall of stomach was freshly adherent to pancreas, which was of blackish-red appearance, with extravasated blood in the tissues about it and some fat necrosis. Gall bladder was free and distended.

Diagnosis. — Acute hemorrhagic pancreatitis.

CASE 6. July, 1898. C. H., aged twenty-six, male.

Past history. — Very alcoholic.

Present illness. — One and one-half hours before being brought to Massachusetts General Hospital he was found by a doctor to be very cyanotic and in a state of collapse. He was vomiting and was slightly jaundiced. Abdomen was distended and rather rigid. Temperature, 100.8°. White count, 11,200. He died the same day.

Autopsy (medico-legal) showed acute hemorrhagic pancreatitis.

CASE 7. August, 1898. F., aged forty-four, female.

Past history. — Not recorded.

Present illness. — For two days she had pain in right hypochondrium. She entered Massachusetts General Hospital in poor condition, with temperature 100°; pulse, 135; respirations, 28. Examination showed a fat woman with a tumor the size of a cocoanut at umbilicus. At operation, tumor was found to be a twisted cyst of the omentum. This was removed and an omental hernia was also discovered. Nothing abnormal about pancreas was noted. She was sewed up tight and died a week later.

At autopsy there appeared fat necrosis of peritoneum. On section the tail and middle portions of pancreas showed softened black and red necrotic areas with cheesy centers. The gall bladder contained a stone the size of a hickory nut. The duodenal mucosa was dark-red, soft and thickened. The urine in the bladder contained sugar.

Diagnosis. — Hemorrhagic pancreatitis.

Case 8. February, 1903. S. P., aged thirty-six, salesman.

Past history. — A year before this he was in Massachusetts General Hospital with pain in right hypochondrium, which he had had at times for seven or eight years.

Present illness. — Two and one-half days before entrance he had another attack of pain felt all over abdomen, but worst in right hypochondrium, right groin and right flank. It became more severe and he began to vomit. Examination showed a slightly distended abdomen, dull in both flanks. Tenderness was most marked in right hypochondrium and in epigastrium. He looked sick. Temperature, 100°. Pulse, 80. He was operated upon the day of entrance. A reddish-brown fluid was free in abdomen. Peritoneum injected with disseminated fat necrosis. Gall bladder and ducts appeared normal. Pancreas was enlarged and hard, of deep purplish-red color. Median incision closed. Five-inch incision along left costal edge. Duct of Wirsung found free from stones. Incision into left half of anterior surface of pancreas showed some areas of necrosis. Drainage was placed to this incision. Patient did fairly well and nine days later was etherized and wound dressed. Pancreas appeared the same, but one third smaller than at operation. In ten days pancreas was again inspected and necrosis found to be not increasing. About six weeks later, owing to signs of abscess formation, an incision was made over gall bladder, which was adherent. An abscess was found in the pancreas and drained. After this he did well and was discharged much relieved. During convalescence sugar appeared in his urine three times.

In answer to a letter sent him this month, seven years after his operation, this patient informs us as follows: Since operation he has had no further similar attacks; he has no digestive disturbance or vomiting, but is constipated and for over three years has had diabetes.

(This case, which was operated upon by Dr. C. A. Porter, was reported in 1903 by Von Mikulicz, to support his theory that the pancreas should be incised.)

Case 9. April, 1904. R., aged twenty-four, female.

Past history. — During four months before coming to the Massachusetts General Hospital the patient had four or five attacks of acute epigastric pain without jaundice.

Present illness. — Four days before entrance she was seized with sudden severe pain in epigastrium; the pain remained constant until entrance. She suffered also from vomiting and constipation. Examination showed a very stout woman, very sick, with temperature, 106.5°; pulse, 136; respiration, 40, and white count, 8,000. There was dullness in the right flank and an indefinite, tender mass below the liver.

At operation the same day considerable free bloody fluid was found. The omentum was dark with fat necrosis. Gall bladder was normal. Pancreas, as it was greatly enlarged and indurated, was incised and drained. Death occurred within two hours. There was no autopsy.

Case 10. September, 1904. S., aged thirty, female.

Past history. — Seven months before entering Massachusetts General Hospital she had an attack of pain in right hypochondrium, associated with jaundice and vomiting.

Present illness. — Four days before entrance she had severe pain in epigastrium and vomited. Felt better the next day. The morning of entrance had a similar attack.

Examination showed a very fat woman, not jaundiced, whose abdomen, except for tenderness in epigastrium, appeared normal. Temperature, 100.4°; pulse, 80; respirations, 38; white count, 21,000. Operation the same day showed much bloody fluid in abdomen and disseminated fat necrosis. The gall bladder was thickened. Pancreas was tremendously enlarged, hard and hemorrhagic. The head was not involved. The body was incised, with the escape of much bloody fluid, a counter incision made and drainage inserted through both wounds. The patient died in twenty-four hours and was not autopsied.

Case 11. Faulkner Hospital. August, 1906. W., aged forty, factory hand.

Past history. — Fifteen years before patient had an attack of pain similar to her present attack, but without vomiting. Three weeks before entrance she again had such an attack. Never jaundiced.

Present illness. — Two weeks before entering hospital awoke with severe pain in epigastrium, which became more severe and extended over abdomen. Continued vomiting ever since. Had not passed even gas by bowels for three days. Examination showed a pale woman with feeble pulse. Abdomen distended, dull and tender in epigastrium and right hypochondrium. Temperature, 102°; respirations, 6; pulse, 120; white count, 31,600. Upon operation a hemorrhagic dark-brown fluid and some areas of fat necrosis appeared. Gall bladder, slightly distended, contained several large stones which were removed. Pancreas three times normal in size, hard, nodular, dark red throughout. Slight hemorrhage was seen oozing from it. Pancreas drained. Collapse and death followed in one and one-half hours. At autopsy a section through long axis of pancreas showed throughout its entire extent opaque, greenish-yellow and often softened areas .5 cm. or less in diameter. A preparation from one of these showed B. coli and streptococcus. There was general arteriosclerosis.

Case 12. January, 1907. B., aged thirty-four, female.

Past history. — In five years before entering Massachusetts General Hospital patient had numerous gall-stone attacks without jaundice.

Present illness. — Three days before entrance she was seized with sudden severe pain in epigastrium and vomiting. Pain radiated to the back. Pain became general, but worst in epigastrium. Examination showed an obese woman in collapse. Abdomen distended and dull in flanks. Temperature, 104.5°; white count, 38,000. At operation there was free, greenish-yellow, cloudy fluid. No fat necrosis was seen. Gall bladder was distended, but no stones were found. The case was thought to be one of intestinal obstruction; the intestine was drained and the patient died the same day.

At autopsy, innumerable minute black mulberry-like concretions were found in the gall bladder. A similar concretion completely occluded the ampulla of Vater. No duct of Santorini was found. The mucosa of the duct of Wirsung was smooth, but was coated with faintly greenish-tinged, foul, mucous material.

The pancreas was considerably enlarged, its tissue rather soft; in the head and body were grayish or whitish clay-like, necrotic-looking areas. In the tail such areas were fewer. Some necrotic areas were reddish, yielding foul, red fluid. Some veins were thrombosed. There was a moderate amount of fat necrosis.

Case 13. May, 1907. O., aged forty-five, female.

Past history. — During fourteen years before coming to Massachusetts General Hospital patient had six attacks of pain in epigastrium and right hypochondrium, accompanied by vomiting and jaundice.

Present illness. — Two days before entrance she was taken with sudden pain in epigastrium and vomiting, both of which increased in severity up to time of admission. Patient was a rather obese woman in collapse.

Although she did not appear jaundiced, there was bile in the urine. Her abdomen was distended and tender, without any palpable mass. The white count was 19,500. She was in too poor condition for operation, became uremic and died three days later.

Autopsy.— Abdomen contained brownish, blood-stained fluid and disseminated fat necrosis which extended even to sub-pleural tissues at top of chest. Aorta was moderately sclerosed. The gall bladder contained about fifty whitish calculi. Two calculi were in common duct, which, however, was not dilated. Orifice of ampulla was blocked by a plug of tenacious mucus. The pancreas and surrounding tissues were replaced by dark-brown or red, almost homogeneous, material, with opaque grayish patches and some semi-fluid areas. In the tail, the most affected portion of the gland, was a cavity containing a gritty, sandy, brown substance. The duct of Wirsung was not dilated nor bile stained. No duct of Santorini was found.

Diagnosis. — Hemorrhagic pancreatitis with necrosis.

CASE 14. June, 1907. S. H., aged thirty-six, hotel keeper.

Past history. — Patient had been a steady drinker.

Present illness. — Four days before entering Massachusetts General Hospital, after taking morphia "for his nerves," he began to vomit. He felt something in his epigastrium "give way," followed by severe abdominal pain which soon decreased. His abdomen was moderately tender, with slight spasm to right of umbilicus. There was some tenderness in right loin. White count was 7,400; temperature, 100°; pulse, 90.

At operation the same day his appendix was removed through a lower right rectus incision. Some fat necrosis was seen, and his pancreas, on palpation, seemed somewhat thickened. The wound was closed, however, without drainage. During convalescence he had delirium tremens, which did not prevent his leaving the hospital in three weeks, well.

A note from him one year after operation stated that his condition was better than it had been for years. At the present time he complains of persistent cough and loss of weight, but has had no digestive disturbances.

CASE 15. Faulkner Hospital, August, 1908. A. N., aged fifty-one, housewife.

Past history. — For eight months patient had had "girdle pains" requiring much codeia for relief.

Present illness. — Three days before entrance she had an attack of epigastric pain, not especially severe at first, followed by vomiting. Pain increased in spite of drugs, and patient showed signs of collapse. Abdominal distention then appeared, and just before entrance she suffered a collapse, followed by unconsciousness for one-half hour. Temperature, 99°; pulse, 130. She was operated upon soon after. There were free fluid and numerous areas of fat necrosis in omentum and parietes. Abdomen drained. Her condition did not improve and four days later she died.

CASE 16. Faulkner Hospital, April, 1910. A. H., aged fifty-two, salesman.

Past history. — Occasional digestive disturbance of slight degree.

Present illness. — Two days before entrance, following a dinner of steamed clams, patient had "stomach ache." This continued the next day and by evening there was tenderness in epigastrium and right hypochondrium. Pain also localized in epigastrium. Temperature was 98.6°; pulse, 80; white count, 18,000. The next morning he felt better, but at 8 A.M. white count was 22,000. Between eight and nine o'clock he suddenly felt a terribly acute pain in the epigastrium. The upper abdomen was rigid. He was thought to have a perforated duodenal ulcer, and operation was at once performed. There was some free fluid, and the omentum, which was relatively much fatter than was the patient, had a peculiar, porky appearance. Gall bladder appeared normal, but could not be quite emptied. The head of the pancreas was thickened and presented an area, about an inch and a half in diameter, of reddish tissue with a white center. Drainage was led to pelvis and pancreas and into gall bladder. The patient did well and recovered. During convalescence, the tissues about the fistula to pancreas showed auto-digestion.

Gangrenous Pancreatitis.

CASE 17. August, 1894. C., aged fifty-one, male, collector.

Past history. — Unimportant.

Present illness. — Six days before entering Massachusetts General Hospital he had an attack of vomiting followed by pain in left iliac fossa. The vomiting has continued, and his stools have been streaked with blood. Examination showed a doughy tumor extending from right costal margin obliquely across abdomen above umbilicus and reaching left iliac fossa. Rectal examination negative. Temperature at entrance, 100.5° F.; pulse, 100.

Operation the following day showed omentum rolled up in a mass covered with fat necrosis. A hole made through this revealed thickened tissue which bled freely. Drainage. Patient died in three days.

Autopsy showed marked arteriosclerosis. Greater peritoneal cavity normal except for fat necrosis. Lesser cavity walled with dirty black exudate. Central portion of pancreas disorganized. Thrombosis of splenic vein.

CASE 18. April, 1897. F., age forty-nine, grocer.

Past history. — A similar attack five years before admission to Massachusetts General Hospital.

Present illness. — One week before entrance he was seized with a sudden griping pain in epigastrium, from which he became unconscious. The pain immediately subsided, he vomited and felt well enough to get about. His malaise continued and he came to hospital. Examination showed a fairly well-nourished man, slightly jaundiced. Abdomen generally tympanitic and tender, with resistance and dullness in right hypochondrium. Temperature, 101.8°; pulse, 100; respiration, 36. At operation clear free fluid was found in abdomen. The omentum was adherent about a pale, friable, necrotic mass. This was drained, but the patient died within three days after operation.

Autopsy showed peritoneal fat necrosis. There were four or five small black stones in cystic duct and neck of gall bladder, but common duct was free. The tail of the pancreas presented about 3 cm. of dark-red, somewhat softened necrotic-appearing tissue. In the head were opaque, whitish, soft spots like abscesses. "All the fat about the pancreas was changed to a dirty, black, semi-fluid, shreddy, necrotic, grumous material." Bacillus coli and staphylococcus aureus were grown.

CASE 19. July, 1906. L. L., aged forty-four, female.

Past history. — Unimportant.

Present illness. — For three months before coming to Massachusetts General Hospital she had pain accompanied by vomiting on an average of once a week. She had lost weight. Abdomen was full, rather rigid in upper half, especially on the right. Liver was enlarged and patient was jaundiced. Temperature, 101°; pulse, 120. After three days in the hospital she was operated upon. Gall bladder appeared normal. Omentum was rolled up in a mass and necrotic. No pus was found, but pancreas throughout was "more or less necrotic." Drainage was placed to pancreas. The patient recov-

ered and left the hospital with a discharging sinus two months after operation.

At present her whereabouts cannot be ascertained.

Suppurative Pancreatitis.

Case 20. April, 1898. E. H., aged twenty-eight, female.

Past history. — Not important.

Present illness. — One day before entering Massachusetts General Hospital patient had some abdominal pain, most severe in epigastrium. She worked that day, but the following night vomited. She came to hospital with temperature, 103°; pulse, 120; white count, 21,600. She was not jaundiced. Her abdomen was slightly distended and tender everywhere, with slight spasm in right hypochondrium. At operation a small abscess containing about 1 dram of pus was found in the head of the pancreas. Gall bladder was normal. Abdomen was flushed out with salt solution and abscess drained. The patient recovered and was discharged one month later. She has not been heard from since.

The following case is entitled to a place under each of the three preceding classes of pancreatitis.

Case 21. July, 1899. O'B., aged thirty-four, bartender.

Past history. — Not obtained.

Present illness. — Had been drinking heavily for three weeks. Two days before coming to Massachusetts General Hospital he woke with severe pain in epigastrium and vomited. The pain continued and he entered hospital with temperature, 99.8°; pulse, 130; respirations, 20; white count, 9,200. Except for distention and dullness in flanks, his abdomen showed nothing abnormal. Operation disclosed free coffee-colored fluid and fat necrosis. Gall bladder was normal. Head of pancreas was enlarged and injected. Abdomen was washed with salt solution and a wick placed to pancreas. For twelve days he did well. Then his temperature rose, white count went up to 26,000 and he began to vomit. Four weeks after the first operation he was again operated upon. An abscess of the omental bursa, with the pancreas entirely sloughed away, was found and drained. Two days later the patient died.

There was no autopsy.

SOME OBSERVATIONS ON THE SURGERY OF THE VASCULAR SYSTEM.*

BY JOSHUA C. HUBBARD, M.D., BOSTON.

ARTERIOVENOUS ANASTOMOSIS FOR GANGRENE.

What treatment is offered at present to the patient who seeks advice for senile gangrene? Amputation so high above the gangrenous area, even though it be small, that the patient is shocked at its extent, and the surgeon dreads the crippling effect of the operation for his patient, appreciating but too well that he is too old to become at all skillful with the use of crutches or an artifical leg. What is to be said to the younger men with pre-senile gangrene? Much the same. The amputation must be equally high, though its effects may be less crippling, as the patient is young enough to learn how to get about by artificial means.

How attractive would be an operation which would offer to the patient improvement in the circulation sufficient to prevent the increase of impending gangrene, or to make it safe to remove only the gangrenous area itself, with a fair certainty that the flaps would heal kindly. How eagerly would both patient and surgeon accept such an operation. It is to review the possibilities of such a procedure that this paper is written.

In 1906 Carrel and Guthrie [1] demonstrated by experiments on dogs that it was possible to divide the femoral artery and vein and then to anastomose them in such a way that the circulation in the leg would be completely reversed, the vein carrying arterial blood and the artery returning venous blood. They demonstrated beyond dispute that the technic was surgically possible on animals and that the joints would remain patent. At first thought it would seem that the valves in the veins would offer an obstruction to the reverse flow. They showed, however, that the valves, in a comparatively few moments, yielded before the arterial pressure. Inasmuch as senile gangrene is due to an insufficient amount of blood reaching the part through the arteries, the suggestion was made by them that such an operation might be of benefit to man in the treatment of this condition. Could the blood be sidetracked and delivered to the part through the veins, a greater amount of blood would necessarily reach it, since the capacity of the veins is much greater than that of the arteries.

A knowledge of the pathology of the two conditions, senile and pre-senile gangrene, is necessary for a clear understanding of the mechanics of the operation. For the operation to be beneficial, the deep veins must necessarily be patent.

Freeman [2] mentions two theories advanced to explain senile gangrene:

1. Winiwarter believes that senile gangrene is due to a definite form of inflammation of the internal coats of the arteries (endarteritis) which produces narrowing and finally obliteration of the channels by the formation of granulation tissue.

2. More recent studies by Zoege-Manteuffer and Weiss have shown that the principal if not the sole cause is sclerosis. This narrows the caliber to a point where thrombosis easily occurs on the roughened surface, thus completing the obstruction. The arterial sclerosis may be either diffuse or nodular, or both together.

Buerger [3] finds that the obstruction to the flow in pre-senile gangrene or thrombo-angiitis obliterans comes from the formation of obturating thrombi which later become organized and canalized. The process is not secondary to the existing gangrene and occurs even when no

* Read before The Massachusetts Medical Society, June 7, 1910.

gangrene is present. He finds that the thrombi may form in the veins as well as in the arteries.[4] In nineteen cases of this condition the arteries were more or less affected. There was obliteration of the deep veins in seven and of a large part of the internal saphenous in one. Because of the extent of the disease, the veins in six offered no better channel for the blood than the arteries. In these six, therefore, arteriovenous anastomosis would have been a useless operation. To determine the patency of the deep veins, he has suggested a simple test. The leg is allowed to hang down a sufficient length of time for a fair degree of cyanosis to appear. The veins are then obliterated by a tourniquet above the knee; the leg is then raised high and the bandage loosened sufficiently to remove pressure from the deep veins. If the cyanosis is slow in disappearing, or fails to disappear, it is a fair conclusion that the deep veins are not functioning.

The inferences to be drawn after this examination has been made are, unfortunately, not infallible. This was shown recently to me in a case seen with Dr. L. E. Somers, of Cambridge. A man of sixty-five, whose right leg had been amputated for senile gangrene, was seen because of discoloration of the left foot. It was evident that gangrene was about to begin in that foot also. An attempt, therefore, seemed justifiable to save the leg. With a tourniquet tight about the thigh, the leg was allowed to hang. The cyanosis of the foot increased within a few minutes. The tourniquet was then loosened sufficiently to control the superficial veins and the leg raised, and the discoloration disappeared. I felt, therefore, that the deep veins were patent. At the operation the femoral vein and the artery were firmly adherent together. The artery contained a clot, and the lumen of the vein was obliterated by an organizing thrombus, through which small canals ran in an irregular manner. An arteriovenous anastomosis was, of course, out of the question.

In an old man whose gangrene presents the appearance of ordinary senile gangrene, there may be an intermixture of a former condition of thrombo-angiitis obliterans with the senile condition. It would be well to try Buerger's test before attempting an arteriovenous anastomosis, but not to put too much importance on the result. Certain cases of gangrene of the lower extremity will, undoubtedly, be found to be unfit for the operation; others will, however, remain where there is no physical contra-indication for carrying out the operation.

When a new surgical cure is under discussion, it must fulfill satisfactorily three tests before its place is assured. (1) It must be demonstrated that the procedure can be carried out on animals. (2) That the surgical technic is possible in man. (3) That the operation when completed is of benefit.

The first requisite has already been fulfilled by the experiments carried out by Carrel and Guthrie, as previously mentioned. It is to be my object to convince you that the second requisite has also been fulfilled by three recent cases. The third requisite must still be left undecided, although it would seem that it were about to be fulfilled. The three cases mentioned above I will now cite in some detail.

Weiting[5] reports the following case which evidently comes under the classification of thrombo-angiitis obliterans. A man forty years old had his right leg amputated a year previous because of spontaneous gangrene in the foot. When he came under observation, the left foot and the ankle were livid and cold to 15 cm. above the malleolus. When the foot was raised it became white; shiny edema was present, as well as paresthesia and pain. Under spinal anesthesia the femoral vessels were cut down upon; the vein was tied below the junction of the internal saphenous; the artery was divided above the origin of the profunda; the proximal end of the artery was then intubed into a lateral incision in the vein below the tie and caught in place by sutures. A month and a half after the operation, there was scarcely any difference in appearance between the left foot and a normal foot. It was warm and free from pain. In two months he was discharged from the hospital.

Second case by Hubbard.[6] A man of seventy-seven years with threatened gangrene of half the foot and much pain in the leg. No pulsations in the vessels. An arteriovenous anastomosis was done under ether. At first the pain was much relieved by the operation, and the color of the foot was decidedly improved. On being allowed to hang the foot down, seven days later, slight edema appeared which gradually increased until the leg became very much swollen and woodeny in feeling. The circulation in the foot continued to improve, but the pain was unbearable, and five weeks after the anastomosis the thigh was amputated below the site of the anastomosis. At the amputation arterial blood spurted from the femoral vein.

Third case by Muller.[7] Patient fifty-one years old. When admitted he had gangrene of some of the toes. Under spinal anesthesia an end-to-end anastomosis was carried out by the Carrel method. Complete reversal was not attempted. Following the operation, a line of demarcation developed at the tibio-tarsal joint. About two months later the leg was amputated four inches below the knee. At this time the veins showed feeble but distinct pulsation.

In two of these cases it was demonstrated beyond dispute that the arteriovenous anastomosis was functioning after five to eight weeks, and in the first case the clinical evidence is such that it must be taken for granted that the joint was patent. The technic of the operation is, therefore, possible.

As to the permanent benefit of the operation, it may be said that Weiting's case had had no further trouble after two months. In my own case, circulation in the foot was, without doubt, better than before the operation. The pain, however, had not evidently been relieved and extreme edema had developed.

According to Freeman, writing in Keen's "Surgery," the origin of the pain in gangrene is not clear. Two explanations have been offered: The first that it is due to degenerative or inflammatory changes in the nerves, and the second, to the reaction of the nerves to acute anemia. Whether a complete reversal of the circulation would have prevented this, and section of the nerves, as suggested by Bryant and Buck, have relieved the pain, can be learned only by future work.[8] Stretching the internal and external popliteal nerves has given moderate relief to the pain of gangrene, while resection of 5 cm. of them has arrested pain at once. They now advocate simply severing the nerve. This would relieve the pain and give an opportunity for the nerve to regenerate later.

In presenting the advisability of an arteriovenous anastomosis to a patient who has already a slight spot of gangrene, it is fair to state definitely that the operation has no shock; that it is possible, under proper technic, to make a tight joint; that there is a chance of much benefit resulting from the operation; that if it fails he is no worse off than before as to the height of the amputation above the gangrenous area. I am not prepared yet to suggest it to the patient who has no real gangrene present, except under the most extraordinary circumstances, as under those present in the case of Weiting.

DIRECT TRANSFUSION OF BLOOD.

I will turn now to the other branch of vascular surgery in which I, personally, have had experience, namely, direct transfusion of blood. It is to Crile that we owe the successful carrying out of the technic of direct transfusion of blood, and it is from his work and enthusiasm that the procedure has taken a very definite place among the various methods of treatment. There is no question of its efficacy in certain conditions. In other conditions its effects are still under judgment, and in still others it is of no benefit.

Since Crile has described his canula, various men have modified or altered it entirely with the idea of simplifying the procedure. There are now many canulæ on the market, and various methods of performing the operation have been described. It seems to me there are several requisites. In the first place, the canula must be made in several sizes or be adaptable to any size, for it must fit the vessel of the newborn baby as well as that of the adult man. The technic of putting it in place must be as simple as possible, and the means by which it is fastened in place must be sufficiently strong to withstand an occasional pull, as during the half hour or so the blood is running from the donor to the patient it is impossible at times to prevent a certain amount of pull on the joint. Carrel simply sutures one vessel to the other, but this, with the ordinary surgeon, is entirely out of the question. He is not sufficiently skillful to carry out the technic; therefore, some mechanical aid in the operation is necessary.

Various modifications of Crile's canula and technic [9] have been made by Ottenberg,[10] Levin,[11] Vickery,[12] Elsberg,[13] Bernheim,[14] Hepburn,[15] Brewer, Hartwell, and, doubtless, others. Personally, I have finally given up all technics except that described by Elsberg, and my advice to one who wishes to make himself proficient in the technic of direct transfusion of blood is for him to experiment with the various canulæ which appeal to him, and then to finally settle on one and learn how to use it. The technic of direct blood transfusion is very fussy at times. There is no reason why any one who is willing to do a few experiments should not learn how to use a canula, though at times it tries the patience of every one before the operation is finished. I should like to lay stress on the importance of not delaying before attempting this method of treatment so long that the patient is really past recovery. The technic, as I have said, is, at times, difficult, and it may be an hour or two before the blood is flowing properly. It has been my misfortune to have patients die while I was at work and before the transfusion had been completed.

Hemolysis is held up as a danger in direct blood transfusion. It is defined by Crile as a toxic condition, which gains its name from the fact that the red corpuscles are destroyed to a more or less extent. It is thus a toxemia from the transfused serum.

In the ordinary emergency case, where blood transfusion is indicated as a life-saving means, there is no time for carrying out a test for hemolysis, and in my experience I have been fortunate enough to have seen no accidents from the mixing of bloods. I doubt very much whether the test is necessary in cases of hemorrhage of any character or shock. When it is a question of improving the condition of one who has been sick for some time to such a point that he may be operated on, then there comes the possibility of the hemolysis, in which case a test should be made. Pepper and Nisbet [16] refer to a case of hemolysis where the condition appeared after a second transfusion from a second donor. I have transfused a patient a second time, three days later, from a second donor, a cousin of the first donor and a sister to the patient, with no ill-effects.

After the canula is in place, I have found it difficult at times to determine whether the blood was flowing, and have made several mistakes, I feel sure, by being too impatient to obtain results, and have cut out the canula and done the operation over again. I now feel that if one is sure of his technic it is much better to leave the canula alone and wait for from fifteen to twenty minutes before considering the operation a failure and doing it over again. Such a length of time sometimes is necessary to show the first change in the patient. With the first suggestion of restlessness or sighing on the part of the donor, it is well to stop the transfusion, as there then remains but a short time before the donor will feel the effects of the loss of blood.

The dangers of direct blood transfusion have always seemed to me to be more to the donor than to the recipient, because of the dissection of the radial artery close to the numerous flexor tendons

of the wrist. It is exceedingly difficult not to break asepsis when it is time to connect the vessels of the two persons. Should the donor's wrist become septic, one can imagine the disastrous result to the usefulness of his hand. I have always picked out the left hand in those who were right-handed, and so far have had no mishaps.

It has not been my good fortune to carry out a blood transfusion for all the conditions for which it is recommended. There is, however, no doubt, as I have said before, but that in traumatic or post-operative hemorrhage or shock it is a life-saving method. I will mention the following case simply as an example:

I first saw the patient eight hours after operation.[17] A laparotomy had been done for removal of the spleen. When I saw him his pulse was imperceptible at the wrist, 160 at the heart; his body was cold and exsanguinated; his respirations 40 and shallow, and he had not recovered consciousness since the operation. After the transfusion his pulse dropped to 108 and became full and strong at the wrist; his respiration dropped to 18 and became full and deep; his lips and skin became pink and he recovered consciousness, began to laugh and talk, and complained of the pain of the needles in suturing the wound in his arm, whereas before a dissection of his vein had been done without any cocaine and without causing pain.

With toxemia, such as eclampsia, transfusion seems, in certain cases, to be of benefit. Without doubt there are various types of eclampsia (i. e., pregnancy, convulsions, kidney irritation). As yet we do not know enough about these different types to know which it will benefit and which not. Crile reports in his book the recovery of two cases of eclampsia following transfusion, to which I can add another.

(BOSTON MEDICAL AND SURGICAL JOURNAL, Feb. 17, 1909.) Primipara, forty years old. A few days before the date of expected confinement patient had a convulsion, with other symptoms of eclampsia. She was immediately delivered. The urine from a catheter specimen contained a large amount of albumin, much abnormal blood and many casts. In spite of treatment for the first twelve hours after operation the patient's condition remained practically unchanged, remaining dull and apathetic and passing no urine. A catheter passed thirteen hours after delivery found the bladder empty. It was at this time that I saw the patient. After consultation, and at the suggestion of Dr. Patterson, a transfusion was done. At the end of the transfusion the patient was conscious and clear mentally. Six hours after the transfusion the patient began to pass urine spontaneously and passed 90 oz. in the next twenty-four hours, and the bowels began to move for the first time since delivery. On the second day patient passed 160 oz. of urine, which showed no blood and only an occasional cast. The convalescence from this time on went along satisfactorily until recovery.

A second case of a very different type was a failure. Convulsions developed on the second day after delivery. The urine was secreted in fair amount and contained a good trace of albumin. The patient had numerous convulsions and became distended. Various methods of treatment were tried and finally a transfusion was done. As a result the patient became much more quiet, her pulse improved and gas began to pass by rectum. The patient improved for a while and then began to lose ground, in spite of the fact that the kidneys and bowels were functioning. She was, however, still irrational and unable to see. Finally, just before death, she was transfused a second time without any benefit. She died several hours later.

Direct transfusion has been recommended in the treatment of hemorrhage of a hemophiliac to increase the coagulability of the blood, and cases have been reported as cured. Unfortunately, the intervals between the attacks of bleeding may be so long that the treatment is declared to be curative, whereas there has simply not been time for a second hemorrhage. Such a case I saw last fall with Dr. W. D. Small — a young girl who with her periods almost bled to death. Her history had been gone into carefully, and the case was considered one of hemophilia. Finally, after various methods of treatment had been tried, she was transfused, about a year before I saw her. The surgeon reported the case as cured by transfusion. Later, however, she began to bleed again freely with menstruation. When I saw her she was exsanguinated from the loss of blood and within comparatively few days bled to death, her parents objecting to any further surgical intervention.

In another case, recently seen with Dr. H. L. Smith, in a woman who was considered a hemophiliac, a secondary hemorrhage followed an operation on the nose of sufficient amount to cause fainting. Transfusion had, apparently, no effect on the coagulability of the blood, for a few hours later the bleeding from the nose recurred. Ligature of the common carotid was finally resorted to to control the hemorrhage.

A very similar case is reported by Lambert.[18] A child was admitted to the hospital bleeding from a tonsillectomy done on the previous day. She soon collapsed from loss of blood. Her pulse became imperceptible and she lost consciousness. At this time she was transfused. At the end of the operation she was in excellent condition, with a pulse of 124. She was perfectly conscious and all hemorrhage had ceased. About four hours later there was a profuse hemorrhage, lasting for some twenty minutes, which was followed by a continuous flow of bright blood. Her pulse again became rapid and small. There was no bleeding point which could be seen in the bed of the tonsil. The left external carotid artery was then ligated and the bleeding entirely controlled.

In hemorrhagic disease of the newborn, it appears that a large proportion of the babies can be saved. The technic in them, however, is exceedingly difficult, because of the size of the vessels. Such cases, however, are most satis-

factory. The following case was seen with Dr. F. S. Newell and Dr. J. L. Morse:

About twenty-eight hours after birth the baby began to vomit and spit up blood and to pass blood by rectum. A diagnosis of hemorrhagic disease of the newborn was made, and a transfusion done several hours later. Following the transfusion there was no further bleeding.

Crile and Lenhart [19] recommend transfusion as the best treatment for illuminating gas poisoning. I have had one such case, where the man was brought to the Relief Station. He had been found unconscious with a tube from a gas pipe in his mouth. The odor of gas had been noticed around the house for several hours. He was unconscious and bright pink. About an hour after he reached the Relief Station he became conscious, but was hysterical and hard to control. Ether was necessary to keep him sufficiently quiet to carry out the technic of the tranfusion. He left the hospital four days after entrance with no abnormal symptoms. Dr. Drown, resident physician at the Relief Station of the Boston City Hospital, who sees many such cases, felt that this man had taken a sufficient amount of gas to cause derangement of various organs within a few days. He felt that such a case would eventually die. Personally, I have not had sufficient experience with such cases to know.

In closing these few scattering remarks about direct transfusion of blood, it may be fairly said that it is now a recognized method of treatment in hemorrhage and shock, and in hemorrhagic disease of the newborn; that it is perhaps of benefit in some cases of eclampsia and illuminating gas poisoning, and perhaps in hemophilia and as a means of improving the condition of a feeble patient to such a point that an operation may be undertaken.

DISCUSSION.

Dr. Lewis M. Palmer, of South Framingham: Mr. Chairman, I would like to ask the reader what governs him as to the quantity of blood taken from one to the other in transfusion. I think it is very hard to determine how much blood it is wise to take in a given case.

Dr. Hubbard: I think it is very hard to determine how much is taken from the donor. The blood is usually allowed to run until the patient is sufficiently improved, or until the donor begins to show signs of feeling faint. The exact quantity I cannot tell you.

Dr. F. B. Lund, of Boston: In one experience I found very serious symptoms on the part of the donor after running the blood for three quarters of an hour. It was run that length of time because the vessels seemed quite small and we did not think we were getting very much. The symptoms that occurred were that the donor drew one long breath, his jaw dropped, and he went through all the motions of dying, but rapidly recovered on elevating the feet.

I have been limited in doing transfusions by the fear of doing them in cases of hopeless cancer. One owes some responsibility to the donor. And I do not like to transfuse a patient before an exploratory operation on the abdomen, because I have taken blood from a man to brace up a patient so that he would stand an operation, and found the patient I was operating on had a serious malignant disease; in such a case I feel that I have done the donor a wrong. Under such circumstances my procedure has been to do an exploratory operation first and find out whether the case is malignant, and then, if necessary for other symptoms, to do a transfusion. Nine times out of ten at exploration you will find that transfusion, if you had done it, would have been unnecessary.

Dr. Hubbard: It is important to emphasize the necessity of watching the condition of the donor during the transfusion. The effect of the loss of blood appears usually suddenly. The first evidence comes from the character of the respiration. Strangely enough, the pulse changes very little until it suddenly becomes very poor. As soon as the donor begins to take an occasional long breath or sigh it is time to stop the flow, for within a few moments, if the flow is allowed to continue, he may become very pale, his pulse of very poor character, and he may faint with relaxation of the sphincters. The condition is very alarming. Fortunately those that I have seen have regained consciousness within a few moments. It may require, however, several days for the donor to regain a normal condition.

TWO UNUSUAL CASES OF DISEASE OF THE MAXILLARY ANTRUM.*

BY J. PAYSON CLARK, M.D., BOSTON.

The cases which I shall report to you this evening have not only interested me very much, but have been very instructive. I have never, that I can recall, seen any other cases exactly like them, nor have I seen just such cases reported. Dr. Algernon Coolidge, Jr., has seen one or two cases which resemble them. They also have many points of similarity to some of the cases of hay fever and asthma reported by Dr. Jacob E. Schadle which were cured by treating the maxillary antrum. I shall speak of some of these cases again later. Dr. W. E. Casselberry has reported two cases of "serous" disease of the antrum and has given a number of references to literature.

* Read at a meeting of the New England Otological and Laryngological Society, March 30, 1910.

The cases which I have to report might very appropriately be called "mucous" disease of the antrum. Their chief points of difference from Casselberry's cases are the presence of a thick viscid tenacious mucus in the antrum with an apparently unusually large ostium maxillare, while in serous disease the antrum contents is thinner so as to be easily drawn into an aspirating syringe, and the ostium is extremely small or completely obstructed. Also in the mucous disease the vasomotor symptoms are prominent, while they are much less so or even wanting in serous disease.

CASE I. Miss H., age thirty, was referred to me on account of frequent attacks of what she called cold in the head. She had had these attacks for a good many years, but had put off consulting a physician because of her dread of operative interference. Finally she suffered so much and so frequently from nasal obstruction that she was persuaded by her relatives to seek relief. I saw her first on Nov. 2, 1903. Examination showed a deviation of the septum to the left, with a marked thickening or ridge at its base, especially obstructive rather far back in the nose. The turbinates in both nostrils were swollen and the right lower turbinate hypertrophied. There was considerable polypoid tissue in the left middle turbinate region. The patient was given a wash containing salt, bicarbonate of soda and borax. On Nov. 9 the nasal wash was omitted, as it seemed to aggravate the swollen condition of the mucous membrane. Some of the polypoid tissue was removed by snare. On Nov. 11 a portion of the hypertrophy of the right lower turbinate was removed by snare and the patient was given normal salt solution for a nasal wash, and citrate of lithia internally. On Nov. 18 the right nostril was quite clear and the nose had been much better for three days. I then did a Watson-Gleason operation on the septum, at the same time removing with a saw most of the ridge. At the two subsequent visits I removed the rest of the hypertrophy of the right lower turbinate and a small polyp from the left middle turbinate region. The septum operation was a success and the note on Jan. 20, 1904, says: "Both nostrils clear. Question if there may not be ethmoiditis on the left, as there is some mucopurulent material in that region." The patient now had no annoying symptoms, however, and could breathe well through the nose, so nothing more was done. I saw her again on April 6, when I removed some polypoid tissue from the left middle turbinate region. No pus could be seen. I did the same thing on April 13 and 23, May 7 and June 10. All this time she was breathing well through her nose and had no nasal trouble. On Jan. 5, 1905, she came to my office with the history of a "cold" for several weeks. The left nostril was obstructed by swollen edematous mucous membrane bathed in a watery secretion. The right nostril was comparatively clear. She complained of a dull pain in the teeth of the left upper jaw. On transillumination, both antra were dark. On account of the dental symptoms on the left, an exploratory puncture was made into the left antrum through the inferior meatus and the antrum irrigated with a warm boric acid solution. One large mass of thick very tenacious mucus literally flopped like a big oyster into the basin. It had a somewhat reddish-brown tinge, probably from blood pigment. The condition responded readily to treatment and, after three more washings, on Jan. 18 the solution used in washing came out perfectly clear. She was not seen again until Nov. 1, when she came with a similar story of a "cold" for a few weeks. The symptoms were as before distinctly on the left side, and in washing the antrum in the same way an equally large mass of mucus, almost identical in every way with that washed out nine months before, appeared. On Nov. 4 and 20 smaller clumps of mucus were washed out, and on Nov. 27 the solution came out clear. Each time the swelling in the nostril and other symptoms rapidly disappeared as the trouble in the antrum subsided. In October, 1906, the nose was stopped again for a week or two after a visit to the seaside, but the patient recovered from this attack without treatment. On June 21, 1907, polypoid tissue was again present in the left middle turbinate region. I removed it and on June 27 washed the left antrum as before, obtaining two small clumps of thick mucus. Recovery was again prompt under the same treatment. I saw her again on Sept. 17. She said she had suffered from hay fever all through August. She had never had it before. On June 6, 1908, the nose was clear, but it had been stopped at times; there were no polypi in the left middle turbinate region, but the mucous membrane of the turbinate was somewhat edematous.

Dec. 10, 1908: "The nose has been stopped more or less for several weeks. The left nostril looks well, but now the turbinates on the right are swollen and edematous. There is some thick mucus under the middle turbinate, apparently coming from the antrum." The right antrum was washed through a trochar puncture in the inferior meatus and several clumps of thick mucus washed out. The right antrum was washed again on Dec. 28, and the solution was clear except a little blood. The turbinates in the right nostril had assumed their normal appearance. On Jan. 15, 1909, the nose looked well and there was no evidence of mucus in either antrum.

This patient came to see me about two months ago in response to a letter. The nose was clear and both antra equally translucent. On my inquiry how her nose had been, she said, "I have not thought about my nose since I came to see you last."

As I review the history of this case there is one thing that strikes me at once as more than a probability and that is that this trouble with the antra, characterized by acute exacerbations, existed long before I discovered it; indeed, was probably the principal cause of the frequent "colds" with nasal obstruction for which she sought relief. If I had made a practise at that time of transillumination as a routine procedure in nasal cases, as I do to-day, I might have suspected the antrum trouble when I first saw the patient instead of over a year later. Even then I failed to attach sufficient importance to the opacity of the right antrum. Indeed, I think it is more than probable that the undiscovered long-standing inflammation of the right antrum was the cause of the attack of hay fever which she had. It is also interesting to note in this case that of the six acute attacks which she had in the more than five years during which she was under my observation, five were on the left, the side obstructed by the deviated septum, and one on the right. Of the five attacks on the left side, two got well without treatment after the deviation of the septum was corrected.

CASE II. Mrs. X., age thirty-two, was first seen by me on Sept. 26, 1905. She had been troubled a good

deal with obstructed nasal breathing for about a year. She had been treated in New York four years previously for "catarrh" and had had a ridge on the septum in the left nostril removed. Examination showed the right lower turbinate enlarged with a dependent polypoid hypertrophy. Her physician thought an operation not advisable, as she was three months pregnant, so she was given a spray of normal salt solution and another of adrenalin, 1–10,000. For the next month the nose was much obstructed at times by swelling of the turbinates till finally the removal by snare of the polypoid hypertrophy of the right lower turbinate gave some relief. But on Nov. 1 the turbinates and mucous membrane of the septum in the right nostril were swollen and edematous and covered with a watery secretion. On shrinking with cocaine and adrenalin, a string of thick tenacious mucus was seen protruding under the right middle turbinate. On transillumination the right antrum was decidedly dark, while the left lit up beautifully, including the pupil. On Nov. 23 the patient showing no improvement by other treatment, the right inferior meatus was punctured with a trochar and a large mass of thick tenacious mucus having a reddish-brown tinge was washed out. The antrum was washed on Nov. 25, Dec. 1, Dec. 8 and Dec. 16, the clump of mucus expelled getting smaller and smaller and the turbinates gradually shrinking until the right nostril was clear. On Dec. 16 the right antrum was translucent. The patient then went to New York for the Christmas holidays. There she caught cold and returned Jan. 2 with hoarseness and cough. I found an inter-arytenoid swelling which gave me some anxiety for a time, as I feared tubercular laryngitis. This condition, however, got well under local treatment and I did not see the patient again until Oct. 16, 1909, over four years. The right nostril had then been obstructed for three weeks. The nasal mucous membrane was red, swollen and edematous, the right antrum dark on transillumination. I punctured the inferior meatus again with a trochar and washed out a large clump of thick mucus similar to that previously described. The right nostril was at once clearer, but became stopped again on the 19th, when I again washed out some thick mucus. Between this date and the 15th of November the antrum was washed eight times. The last two times the clump of mucus was clear and transparent and about the size of a pea. The antra now transilluminated equally except the right pupil did not light up as well as the left. Dr. J. Homer Wright kindly examined some of this mucus for me under the microscope and found that it contained a number of leucocytes, but no bacteria in the smears. On Dec. 22 the right nostril was again somewhat obstructed, thick mucus was visible under the middle turbinate and the right antrum was dark on transillumination. This was somewhat discouraging. The patient did not want to go through the treatment so soon again, and I did not want to do it if it could be avoided. So I determined to wait for a time, having her use a mild alkaline nasal wash. I saw her again on Jan. 8, 1910, when she was much better. The nose was then fairly clear. On Feb. 2 there were no symptoms and on transillumination the right antrum was again almost as translucent as the left.

Both these cases were young women. In both the attacks of nasal obstruction were almost identical except that in the first case the nasal obstruction was more marked because both antra were affected. In Case II there was also considerable obstruction of the left nostril (the side of the unaffected antrum) due to a sympathetic swelling of the turbinates, but these bodies were not covered with a watery secretion and did not look edematous as on the affected side. The gross characteristics of the mucus were in every way identical. The ostium maxillare was apparently unusually large in both cases. I came to this conclusion from the rapidity and ease with which the large clumps of mucus were expelled.

Dr. Schadle, in his interesting and valuable article on "The Relation of Antral Sinusitis to Hay Fever and Asthma," describes several cases with similar symptoms. In my cases, however, the vasomotor symptoms were not so marked. There was little or no sneezing as a rule with the attacks (except the one seizure of hay fever which the first case had), nor were there any eye symptoms. It will be seen by the following quotations that the material washed from the affected cavities was much the same in his cases as in mine. In the first case reported in the above-mentioned article he says: "Pus was not present, but a large quanity of ropy, muco-purulent material was dislodged and discharged into a drainage vessel by means of injections of a warm Dobell's solution." Of another he says: "What came from the right cavity was thick, bluish in color, and jelly-like in consistency." And again: "Large quantities of a substance resembling milk curdle came from both sinuses. Besides this, mucoid contents, jelly-like in consistency and bluish-gray in appearance, were forced from the cavities." He also lays stress on the large size of the ostium maxillare in his cases. The etiology of this catarrhal inflammation of the antrum is not perfectly clear. Schadle says that in these cases "the abnormal ostium forms the predisposing medium of irritation or infection. Unlike the nose, the antrum, under normal anatomic conditions, is practically a sterile sinus, and, apart from the *very small* ostium, is substantially a closed cavity. When, however, malposition of the ostium exists, or when the opening deviates from its normal size and course, the foundation is laid for the development of infection." If there is a bacterial infection in these cases, why does the secretion remain mucous in character, no matter how long the trouble persists, and not become purulent, as in the common form of sinusitis? The only answer I can make to this question is that the infection must be a comparatively mild one. For we know that in the common head cold the severity is measured by the variations in the relative proportions of the mucous and purulent elements in the discharge. If the ultimate cause is not an infection, I am at a loss to say what it is. It is evident from the history of these cases that the individual who has had an attack is liable to another. The diagnosis of this affection is not difficult, after a careful examination. The symptoms have been sufficiently described in the report of the cases. The nasal symptoms are evidently due to the irritating nature of the antral discharge. Schadle found this discharge to be acid. The prognosis as regards recovery from a given attack is good. If Schadle's theory as regards the causative factor of

a large-sized ostium is correct, it would seem as if some method for reducing the size of the ostium should aid in a permanent cure. What one could do in this direction I am as yet unprepared to say. The rather inaccessible position of the ostium makes the proposition a somewhat difficult one. In the treatment I used a normal salt solution containing 2 to 3% of boric acid and sometimes, after the first few washings, a normal salt solution alone, in order to have as nearly as possible an unirritating solution.

CERTAIN ASPECTS OF THE BACTERIOLOGY OF BACILLARY DYSENTERY.

BY ARTHUR I. KENDALL, PH.D.

(From the Boston Floating Hospital and the Department of Preventive Medicine and Hygiene, Harvard Medical School.)

THE object of this paper is to present very briefly certain facts concerning the bacteriology and biochemistry of the dysentery bacillus and associated intestinal flora in bacillary dysentery; to outline in a few words the fundamental principles relating to their activity in the alimentary canal, and to mention the procedures which are theoretically logical for the restoration of a normal intestinal flora.

Full details both of the bacteriological and clinical aspects of this subject will be published later.

The fundamental principles underlying this work are: (1) The fact that bacteria in the presence of protein (and protein decomposition products) and fermentable carbohydrate select and act upon the carbohydrate in preference to protein in the vast majority of cases. The organisms break down enough protein merely to satisfy their nitrogen requirements in such instances.

(2) In the animal body, carbohydrate likewise can be utilized to a very considerable extent to prevent the metabolism of the body nitrogen.

(3) The majority of bacteria, including those commonly found in cases of bacillary dysentery (*B. dysenteriæ*, *B. coli* and the streptococcus), are facultative in respect to their dietary requirements and attack fermentable carbohydrate in preference to protein or protein decomposition products.

(4) Bacteria acting upon protein produce putrefactive products of various degrees of toxicity, but do not form these products when grown in media containing in addition carbohydrate which they can utilize, since in the latter case the fermentation takes precedence over putrefaction, at least until the sugar is exhausted.

The products of the dysentery bacillus which cause the most harm are largely, if not wholly, protein decomposition products. The formation of these putrefaction products can be prevented if a utilizable sugar is present.

(5) The blood of normal human beings contains about 0.2% dextrose as such.

(6) The normal sugar for man is lactose, a sugar of animal origin, in contradistinction to most other sugars, which are of vegetable origin. The lactose is utilizable by relatively few bacteria other than those of intestinal origin, while the animal sugars are fermentable by many types of organisms.

The bacterial flora of the intestinal tract in cases of bacillary dysentery is putrefactive, chemically speaking, because there is, as a rule, little or no sugar present in the intestinal tract of the body for them to act upon. This is equally true for those organisms which succeed in penetrating into the body itself, since the small amounts of dextrose normally present in the blood are usually metabolized early in the disease, particularly under a starvation diet.

The remedy for this condition, from the standpoint of bacteriology, is to add an excess of sugar which can be utilized by the bacteria within the intestinal tract and to restore to normal the amount of dextrose in the blood, so that even those organisms which have succeeded in penetrating within the body itself may have an opportunity to act upon sugar rather than upon the nitrogen of the tissues of the body.

Dextrose infusions (2.5% chemically pure dextrose in normal saline solution) tend to restore this normal dextrose, and also to furnish the body with a considerable amount of fluid. The patient is benefited in two ways: (*a*) By protecting the tissues of the body to a considerable extent from metabolism by the body itself, thus acting as a food which is immediately utilizable for the body needs, and (*b*) by providing a certain amount of dextrose for the invading organisms to utilize, thus further sparing the body nitrogen and reducing the production of toxic products by the bacteria themselves.

Feeding lactose by mouth (5% solution) brings about a similar change in the chemistry of the intestinal bacteria. The lactose furnishes food for the patient as well, reinforcing that obtained by the infusion of dextrose.

The intestinal bacteria, acting upon the lactose and its decomposition products (dextrose and galactose), change their chemistry from the putrefactive to the fermentative type, i. e., produce acids, principally lactic, in place of putrefaction products which must be detoxicated by the body if they are absorbed.

The colon bacillus, for example, in the presence of sugar, forms lactic acid and consequently becomes an antagonist of the dysentery bacillus, in place of being a symbiote forming putrefaction products, as would be the case if there were no sugar present. The putrefaction products in such instances (absence of sugar) would be derived from the breakdown of the intestinal secretion if the patient were on a starvation diet.

Coincidently with the changes in the chemistry of the organisms mentioned, bacteria characteristic of the intestinal flora of normal nurslings begin to appear. The most prominent of these

are *B. bifidus* and *B. acidophilus*, principally the former. These two organisms still further antagonize the dysentery bacillus, since these bacteria are energetic producers of lactic acid. They are among the most desirable and beneficial organisms which could be present under these conditions, since they perform the same functions in dysentery cases that they do in the intestines of normal babies, i. e., antagonize and tend to keep down bacterial putrefaction in the alimentary canal.

The after-treatment will not be discussed here, but will appear in detail in a later publication.

Clinical Department.

A CASE OF CROSSED HEMIDYSERGIA AND TREMOR, WITH ASYNERGIA OF BINOCULAR MOVEMENTS: COMMENTS.

BY TOM A. WILLIAMS, M.B., C.M. (EDIN.), WASHINGTON, D. C.,

Memb. Corresp. Soc. de Neurol. de Paris; Memb. Corresp. Soc. de Psychol. de Paris; Memb. Assoc. de la Soc. de Méd. Ment. Clin.; Neurologist to the Epiphany Free Dispensary, etc.

THE following case seems worthy of publication, as it may in the future afford material with which to answer the problem of the anatomical distribution of the cerebello-fugal systems comprised in the rubro-spinal and vestibulo-spinal tracts.

In some respects the patient conforms to the syndrome of Foville (1858) as described by Grasset before the Neurological Society of Paris in 1900. This type consists of a crossed paralysis of the limbs on one side of the body and of the face on the opposite side, along with the loss of power to rotate the eyes to that side. My case, however, differs from the Foville type in that he presents no paralysis, but a most marked dysergia, which, however, in its distribution, is the same as that of the paralysis in the syndrome of Foville.

J. T., colored, aged thirty-two, a laborer, was seen at the Emergency Hospital Clinic of Dr. Dudley Morgan in April, 1908. He complained of inability to walk steadily, and clumsiness of the left hand. While walking in the streets, "silly thoughts," chiefly about wealth, occupied his mind.

The previous and family history is negative so far as can be ascertained in his present slow-witted state.

Present illness. — About six months ago, he began to feel weak and dizzy, and had severe pains in the loins and back of the head and neck, intense enough to keep him awake at night. In this state, he dragged through his work for about three weeks, until he was sent to bed under medical orders, and there he stayed about two months in a lethargic state. After this he was able to sit about the house and to walk a little, but could not return to work for some little time. He had complained of a "misery in the head" after taking his medicine, or when alcohol was given.

Later he returned to work, and states that he could walk quite well and did not tremble. About two months ago, the left hand became clumsy, swallowing was difficult, and the foolish thoughts, generally vague, though about money, began to occupy his mind. About a month ago he began to tremble, and walking became difficult.

Physical examination. — Motility: Face — at rest, there is slight asymmetry of the face, but no drawing of the mouth nor smoothness of the brow, such as occurs in facial paralysis. When movements are made, however, a violent intentional tremor occurs in the right lip, cheek, jaw and tongue, and there is poor control over the mouth. This tremor is at first very extensive and violent; but when the position is maintained for some seconds, the excursion of movement becomes less extensive and more regular, its frequency being about eight to ten per second. The left side of the face does not tremble, but is, of course, moved by the communicated oscillations from the right side.

The speech is slow, slurring, indistinct and thick.

The eye movements are unsteady and difficult to control; but there is no nystagmus. The pupils react well to both the light and accommodation. The movements of the left arm are slow, clumsy and inaccurate, and there is marked adiadocokinesis. Intentional movements are accompanied by a tremor similar in character to that of the face. It ceases when a position has been maintained over ten seconds. There is no muscular weakness. The movements of the left leg are still more incoordinate, and it also drags upon walking. He walks "*aux petits pas.*"

The movements of the trunk are slow, especially at commencement, and poorly maintained, and there is a rigidity which seems to prevent ready bending movement of the right side. The eyes are also unsteady when turned to the right. On protrusion of the tongue, its right side is agitated by a similar tremor, which almost ceases in about ten seconds, after which interval there is also more control over the facial trembling.

In the left arm there is slight asthenia, considerable impairment of the attitude sense, decided clumsiness and marked impairment of the diadocokinesis. There is also an intention tremor, finer than that of the face, and not maintained more than ten seconds. The general sensibility is very acute and there is no true muscular weakness.

Rotation tests show no anomaly of vestibular sense; the pupils react well to light and accommodation.

The movements do not tend to continue when the resistence is removed, and there is recoil. There is no atonia.

The sensibility is not impaired, with the exception of the notion of attitude in the left arm. There is no anomaly of discernment of rotation.

Reflexes are exaggerated on the right side; but there is no flexion of the great toe on stroking the sole.

Psychic examination was not systematic; and, beyond his dull and confused state, I could find no definite gaps in the memory, attention, perception or judgment. There had been causeless crying, and he had been generally miserable. He stated that there had been no automatic laughter, rage nor emotionalism in general. As to the will, he had felt useless and incapable, but his condition justified this attitude.

Progress. — On April 23, after two weeks of potassium iodide, he was in every way worse and had developed dissociation of the ocular movements. On protrusion, the whole tongue jerked violently forth and back. The control over the facial movements was much impaired. The arms shook violently, and the walk was very difficult. All the movements can be performed, however, when he is emphatically urged.

The speech is very uncertain, and toneless.

When binocular fixation is attempted, asynergic dissociation occurs. The kaleidoscopic series of squints which ensues produces a most weird effect. When

either eye is closed, however, the other can perform all movements, although the right eye only does so with much difficulty and wide tremor. On looking widely to the right with both eyes open, the left eye moves across normally, while the right fails to follow sufficiently. The same phenomenon occurs with the left eye when the gaze is directed towards the left. In each case, vehement urging overcomes the motor incapacity, and the eyes for the moment fix the same spot, the laggard, however, quickly relapsing. When he endeavors to fix with his gaze a point 18 inches distant, he sees double, and the optic axes are noticed to converge.

April 30 he had been taking hydrargyri iodidum gr. ¼ t.i.d., and can now converge and externally rotate the right eye in binocular vision with less difficulty and urging than before, though he cannot maintain the position completely and though diplopia still exists. The diadocokinesis and incoordination of the left leg and arm have improved, and he can better control the protrusion of his tongue. The face trembles less, but his attempts at grimaces are accompanied by associated movements, especially in the left finger. There is no apparent asynergia revealed by the leaning back or chair-mounting tests.

May 4 the ocular movements are better performed; there is less ataxia. The speech is clearer, but the diadocokinesis is still much impaired.

Nov. 15. He failed to return to the hospital during the summer, and the mental symptoms and trembling became much worse, but two months ago a local practitioner accidently treated him, and caused a remission of the *debacle*. When examined, he presented much less tremor of the right cheek, though now the whole tongue trembled coarsely, somewhat in the same manner as, though less extensively than, on April 23. The movement is more of a dysmetric than of a trembling kind. The control over his facial muscles in general is poor, though he can succeed after some effort to elevate and depress the eyebrows. He is unable to whistle. There is no longer dissociation during binocular vision, and all the movements can be effected, although with slowness and difficulty.

The control of the limbs, more especially the left, is slow, hesitating and trembling. The right hand when at rest on his knee exhibits an oscillatory tremor like that in paralysis agitans. This he can inhibit quite easily. When he extends the arms, they move up and down rhythmically through a space of about an inch, and at a rate of about six per second. With the left hand and arm he is particularly clumsy, failing to button his coat; and when he endeavors to touch any distant object, moves it with a series of jerks. The speech varies, sometimes being thick and indistinguishable, and sometimes quite clear. The tendon reflexes are much exaggerated. The examination was very difficult on account of his suspiciousness and unwillingness to make the movements requested. His parents state that he can do light work in the house, but that he loses himself in the streets and sometimes laughs without cause, though he never cries unless beaten, as for disobedience and gluttony, for he has become very voracious.

The outstanding features of the case are hemi-asynergia and intentional tremor of the left arm and leg, intention tremor and possible asynergia of the right face, and tremor of the right tongue. Along with these occurred a dysarthria and exaggeration of the reflexes, a fugitive diminution of the attitude sense of the left arm and a temporary dissociation of the ocular movements and apparent enfeeblement of the movements of the right eye, more especially in levo-gyration.

It is unlikely that the pyramidal tract is seriously if at all affected, for the sign of Babinski is not present and there is no true spasticity nor inability to perform any movement, the incapacity merely extending to the *co-ordination* of several muscular contractions into a determined act. This attempt on the part of the left hand and right face and tongue always provokes tremor.

Now lesions in the neighborhood of the nucleus ruber[1] are known to provoke tremors without in any way implicating the pyramidal tract. They do so by interrupting the impulses which descend in the cerebello-rubro-spinal tract. The tremors are usually, however, mono- or bilateral, and this is the first case of which I am aware which presents a syndrome comprising a crossed tremor due apparently to a single lesion.

I venture to explain the occurrence by the implication of another system of fibers, viz., the ponto-olivary, which traverse the median raphé on their way from the nuclei of the pons and which are thought to receive their afflux through the cerebello-fugal fibers of the middle peduncle. If those of the left system were implicated on the left side while en route to mediate the kinetism of the facial, trigeminal and hypoglossal nuclei, the lesion which interrupts them would necessarily be upon or near the course of the rubro-spinal tract, which mediates the kinetisms of the limbs and trunk of the crossed side of the body. It crosses, however, in the decussation of Forel almost immediately below the red nucleus, and composes the ventral of the two decussations of that region. Hence, in the aforesaid situation in the brachium pontis, it has already crossed and is on its way to mediate the muscular acts of the side of the body upon which it is now situated. Thus the lesion, if in the left medullary-pontine region, would implicate at the same time the left rubro-spinal tract en route to the left limbs and trunk at the same time as it interrupted the impulses as they passed across from the nuclei of the pons to govern the movements of the opposite right side of the face, jaw and tongue.

There may be much uncertainty in the interpretation of symptoms in any particular case where the cerebellar apparatus is implicated. In the case before us the tremors are very significant of an impairment in the course of the cerebello-rubro-spinal efferent system, as has been shown by the cases reported by Gordon Holmes.[1] In some of his cases, however, the lesion was shown to be more widespread by the additional symptoms, such as a definite oculomotor palsy, outbreaks of crying or laughter without external cause, a rigidity of half the face much resembling that in paralysis agitans, and the hesitating steps of the *marche aux petits pas*.[1]

The emotionalism arises when the ventral thalamic nucleus is affected. This is just a little

forward and to the middle of the nucleus ruber, the part of the cerebellar system implicated in many of Holmes' cases. The oculomotor palsy is, of course, due to interruption of the fibers of the third nerve, which run just internal to the nucleus ruber and through it. The short steps are due to the timidity which comes from the disturbance of the patient's control over synergic movements; for though he can make volitional simple movements as easily as before, yet he has lost the power of combining the movements of different joints into harmonious act, except by the exercise of much volition. This requires close attention, which in turn rapidly induces fatigue, one of the prominent symptoms of defect in any part of the cerebellar apparatus.

Rigidity of the face is, on the other hand, due to an exaggeration of cerebellar influences, either by the cutting off from the cerebrum, or by a lesion which stimulates the efferent fibers of the cerebellar system.

The monotony and tonelessness of the speech again are derived from diminished cerebellar influx. In these cases, speech, like the other movements, is often begun with great slowness and difficulty, and it also quickly tires.

The muscle rigidity may affect the trunk, and may take the form either of the bowed forward attitude seen in Parkinson's disease or, on the contrary, the forced extension and even complete opisthotonos shown by some of Hughlings-Jackson's early cases and one of the author's. We do not yet know what determines these attitudes respectively, though we do know that section of the brain stem between the colliculi produces the state of decerebrate rigidity,[2] of which opisthotonos is a feature. The cause of this is the unrestrained exercise of cerebellar afflux, through interruption of the afflux from the neopallium. The tonic nature of the influence exerted by the metencephalon is shown by the character of the fits caused by intravenous injection of absinthe [3] before and after removal of one cerebral hemisphere. While the pallium is intact, the whole convulsion is a clonic one similar to that in a convulsive phase of an epileptic seizure. After one hemisphere has been removed, the opposite side of the body manifests a rigidity similar to that in the tonic phase of the epileptic fit, while the other side of the body is convulsed, as before, clonically.

Very different is the state caused by *destruction* of the cerebellar apparatus; here muscular flaccidity dominates. It is often so severe that the patient cannot sit up, although individual movements are performed quite well, through the agency of will. Its distribution is homolateral, and it has no relation with the state of the deep reflexes. A useful clinical test in the limb is for the observer, after resisting the patient's movements, to suddenly cease to do so. If cerebellar atonia is present, the patient's limb continues its movements to the extreme point, and there is no recoil.

The tremor in these cases is purely kinetic, but does not always increase towards the end of the movement.

As regards attitude, a very characteristic one is that where the occiput is rotated towards and pulled down to the homolateral shoulder, the face thus necessarily looking upwards and to the side away from the cerebellar lesion. The eyes, however, look in the reverse direction back towards the lesion, or in some cases present skew deviation. This consists of the homolateral eye turning inwards and downwards, while its fellow looks outwards and slightly upwards. Horsley has found [4] this experimentally producible by stimulation of a spot in the neighborhood of Deiter's nucleus, which is known to send decussating fibers into the posterior longitudinal fasciculus, the coordinating path of the ocular movements.

The functions of the cerebellum are both static and dynamic. It is a center of energy and of reinforcement for all movements. It maintains tonus, and is necessary for the harmonious co-ordination of separate movements. Interference with its functions, therefore, leads to asthenia, atonia and astasia.

These perturbations are more manifest when the subject is deprived of ocular and vestibular sensorial aids.

The cerebellar syndrome may be summarized in its clinical aspect by calling it a dysbasia with relative integrity of isolated movements. The walk is not exactly ataxic, for the person does not throw out his legs as does the tabetic; it is that of the drunkard. The upper limbs show incoordination; and clumsiness is often shown in the writing. The speech is generally slow and scanning. This is due to the loss of the tonus-regulation, which normally takes up the slack of the muscles (so to speak) so that they respond quickly to nerve impulses, having little inertia to overcome.

This normal diadocokinesis cannot be accomplished when the cerebellum or the tracts which emanate from or lead to it are interfered with. The lack of tonus, too, is the cause of the asthenia, and the fatigability is due to the need of constant cortical intervention for the regulation of movements. This connotes volition, which is the most quickly tired of all functions. This atony may be so extreme as to prevent walking, the patient falling in a heap when placed upright.

A valuable clinical law is that the fall is towards the side of the lesion. When the head is drawn to one side, it is also generally but not always towards the lesion; but the face will look to the opposite side, as the head is rotated by the sternomastoid of the affected side, and hence must look in the opposite direction. The eyes, however, when turned, look back towards the lesion. An apparent exception was shown by Gordon's four cases.[5]

Asynergia [6] is shown firstly in walking by the trunk not following the limbs. Secondly, in standing, if the patient is pushed backwards, the lower limbs remain fixed even without the

bending of the knees and ankles, which naturally automatically tends to maintain equilibrium in the normal person. Thirdly, on endeavoring to sit up, the thighs flex and the heels fly up in the air, and, fourthly, in touching with his foot an object above and in front of him, the patient does so by the movement of the thigh succeeding that of the leg, and jerking like a mechanical doll. Fifthly, by intentional tremor of the hand and arm,[9] and of the ocular movements (nystagmus). All this is generally combined with an exaggeration of the power of static equilibrium.

The deep reflexes may be exaggerated on the affected side.

It is very important diagnostically to determine the complete integrity both of the sensibility and the intelligence, for lesions of the frontal lobe sometimes give rise to a dysbasia not very different from cerebellar titubation.[7] When a neoplasm is in question, the situation of the headache and tenderness on percussion should not receive too much stress, though they are valuable if they do not conflict with the physical signs. When it occurs, the implication of cranial nerves and the sensory tract is usually upon the side of the lesion, though in one extraordinary case of Guldenarm [8] there was left facial palsy, neuralgia, mydriasis and tendency to fall to the left, due to a fibrous sarcoma below the right tentorium. It was the size of an apple and crowded the pons against the left side of the basi-occiput, thus causing the contra-lateral symptoms.

Tumors of the vermis are apt to cause falls backwards, stiffness and extension of the neck, and opisthotonos, along with the foregoing symptoms.

But there was hardly a question of a tumor in our case, for it was most unlikely that so much retrogression could have occurred in symptoms affecting so important a region as the bulb-pons had a new growth been present. Moreover, mercury seemed to be the beneficial agent. Although no lumbar puncture was permitted and the Wassermann test was not then available, yet syphilis was a very probable cause of the symptoms. A basal meningitis causing the abundant exudation followed by absorption so characteristic of the Frascatorian lues could have interfered with both abducens nerves and prevented external movement, but such a lesion could not account for the loss of binocular movements, while those of the eyes singly were retained. Hence, even though meningitis was probably present, it is certain that central lesions also existed in very close proximity to the fasciculi which mediate the activity of the nuclei of the ocular nerves. Indeed, the ocular dysergia was merely a part of the general dysergia syndrome, and, like the latter, was not complete, but was mainly homolateral.

The permanence of the symptoms make it likely that the destruction or interruption of tracts in the mid-brain and isthmus were due to gummatous or arteritic ischemia, a common enough phenomenon, and the interest of the case lies in the rarety (for I have found none other like it) of an attack of the efferent coordinating mechanism of the cerebellar apparatus, the distribution of which attack resembles that of the syndrome of Benedict (type Foville) where the cerebrospinal system is concerned.

A POINT IN THE TECHNIC OF THE USE OF NITRATE OF SILVER IN THE TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA.*

BY GEORGE L. RICHARDS, M.D., FALL RIVER, MASS.

ALTHOUGH suppurative otitis media has become less frequent since the operation for the removal of adenoids and the early treatment of the acute cases of suppurative ear trouble have become more general, many such cases, both acute and chronic, still exist and require treatment. Theoretically, in chronic suppurative otitis, the actual removal of all of the diseased tissue — the so-called radical operation — would seem to be indicated, and there are cases where no other operation can be considered. In many other instances radical surgery will be refused by the patient on account of the loss of time, the expense and the absence of symptoms which to the patient and his friends seem to demand so severe an operation. Even where the radical operation has been done, the results have not always been entirely pleasing to the operator or the patient, as the suppuration has not always stopped. It is difficult to find sufficient material with which to epidermize the enlarged tympanic cavity. Skin grafting has been used, but it is not wholly successful. The new mastoid flap of Dr. Leland is another attempt to accomplish this result and lessen the time of healing, and marks a distinct advance in radical mastoid surgery.

In the absence of urgent symptoms, conservative measures are tried, and the variety of these shows the difficulty of attaining the desired result, which is drainage and the cessation of the secretion. Adequate drainage has been hard to get on account of the anatomic arrangement of the structures with which we have to deal and their relation to the mastoid cells, antrum and attic.

Syringing has its advocates and is valuable, but unless the drum membrane be entirely gone, or nearly so, it is difficult with any type of attic syringe to adequately reach and remove all of the

* Read before the New England Otological and Laryngological Society, March 30, 1910.

débris or purulent material which is present, and even then it is not always possible. Furthermore, the attic syringe is painful in its manipulation unless the patient possess sufficient self-control to sit perfectly still and the hand of the operator be very steady. Suppurative ear cases with small perforations do not do so well as those with large ones. This is probably wholly due to the inadequate drainage. In all cases of suppurative ear disease, especially in children, it is essential to look out for adenoids, even though the other symptoms of adenoids are not present. Many powders have been used in the treatment of suppurative ears, and in many cases they seem to do a great deal of good. They are all open to the objection that they cannot, as a rule, be brought into direct contact with the diseased area unless the perforation be a very large one. Solutions of silver nitrate and other caustics have been applied on the cotton-tipped applicator directly to the diseased area, and frequently with good results. Very often there is the same difficulty in reaching all of the diseased area as in the case of syringing and powders.

To obviate, in a measure at least, this difficulty, I have for a few months been using silver nitrate in a somewhat different manner than formerly, and so far with a measurable degree of success. The procedure is a simple one, and I recommend its trial in suitable cases. If it fails, no harm will have been done. The method is as follows: Cleanse the suppurative area as thoroughly as possible, doing this very carefully, using syringing, wiping and suction as may be needed, and removing any polypi, granulation or débris that may be present. If the perforation is very small, enlarge it, but in the cases in which I have used the silver, this has not been necessary. Lay the patient's head over so that the affected ear lies uppermost and absolutely horizontal. Instill with a dropper a sufficient quantity of the nitrate of silver solution to nearly fill the external canal. Keep the head in the horizontal position for five minutes, then dry the canal thoroughly and put in a light wick of cotton or gauze. I begin with 3% silver solution, and, if necessary, gradually increase until I use 20%. As the silver does not penetrate very deeply, owing to its forming a coagulum at the point of application, it will in most instances have to be used a number of times. Few patients will object to this and will almost always prefer to make trial not only of one but many methods of local treatment before consenting to the radical mastoid or even to ossiculectomy. The diseased area, so far as it is visible, shows white when examined. The treatment is repeated from every other day to once a week, according to the nature of the case and the ability of the patient to follow up the treatment. The silver works best in cases where the probe shows but little bare bone and but limited bony destruction. In the presence of extensive caries, it is doubtful if it would have much value. As a rule, the application is painless, and in only one instance have I seen any reaction. In that case there was pain for a few hours, but the ultimate effect was excellent, resulting in complete healing of the suppurative ear, which had lasted for years. Occasionally the solution goes down the Eustachian tube, causing some annoyance. I do not by any means claim that this method is always successful or that it displaces the radical operation. It is simply one of many procedures that may be tried in these cases, and it has the advantage that by gravity the silver solution is brought into very nearly direct contact with all the diseased area.

I have no series of cases to offer, not having gone over my records to determine in how many cases I have used it. Five illustrative cases are appended as showing the type of cases in which I have found it useful; many more could be given.

Case 1. A. G., age three, with a history of having discharge from each ear for three years, bloody for the last year. Chloroform required for examination. Polypi in each ear. Curetted lightly on several occasions, each time under chloroform, until all of the granulation tissue was removed, then applications of nitrate of silver were made every other day for two months, at the end of which time each ear was dry. This was a case of extensive destruction of the middle-ear structures of the child, and at first it seemed as though a radical mastoid operation would be required on each ear. By continued treatment of cleansing and stimulation with the silver, both ears were brought into good condition and without apparently much loss in hearing. Of course it is possible that the suppuration may start up again; if so, the same method of treatment will be used, as it seems to me desirable to avoid the radical mastoid in the young child if possible.

Case 2. Mrs. L., first seen by me in 1900. The right ear had run for six months and the left one for several years. The margin only of the left drum remained, and in the right ear there was no evidence of any drum visible. The remnant of the left drum was removed, together with the malleus, which was carious. There was cholesteatoma in the attic. As there was pretty fair hearing, and great tendency to dizziness, the ears were treated locally from May until September, at which time they were both dry, the treatment consisting of syringing and gauze wicking. In 1901 she returned, and again in 1902, some cholesteatomatous débris being removed at each time. I did not see her again until 1909, when she returned with both ears discharging and a large polyp in the right ear. This was removed and the instillations of nitrate of silver used in each ear at intervals of five days. In four weeks the right ear was dry and in six weeks the left one was also dry. No syringing was used. Each ear was carefully cleansed, and solutions of first 3% and afterwards 12% were used in the manner previously described. There is still pretty fair hearing in each ear, and it seems to me that conditions are better for her hearing than if a radical mastoid had been done in 1900. The ears have dried up quicker under the nitrate of silver than they did under the previous treatment. That the cure will be any more permanent I would not say; I am under the impression that it will be.

Case 3. M. B., a girl of seventeen, first operated on radically by me for subacute mastoid after a Wilde's incision in January, 1903. She recovered and was not seen again until Feb. 27, 1909, when she returned with pus in the external canal and a temperature of 103. She had worked in the mill until noon of this day, and said that up to this time there had been no trouble whatever in the ears. The mastoid was re-operated upon, revealing the fact that some cells had evidently escaped removal at the time of the previous operation,

especially along the borders and above and behind, these having become reinfected. As at the first operation there was a fistulous tract directly over the entrance to the mastoid antrum and a portion of the periosteum was very much necrosed, a radical operation was done. In doing the secondary operation I found it difficult to make a proper flap to cover the opening, as a considerable amount of the flap of the former operation was more or less cicatricial. The girl was in poor condition, and the convalescence from the operation was very slow. She had general anemia, acne and boils. After her discharge from the hospital the posterior wound healed very slowly, and at one time there was a small fistulous tract leading from the tympanic cavity. She was again given ether and the area curetted. The curette went backward and upward, and seemed to strike an area of bare bone as though there might be a small sequestrum. On carrying the probe backward, it went either through the dura mater into the cerebral cavity or else through the opening of the foramen ovale into the labyrinthine cavity, but it was impossible to determine which. A rapid flow of almost colorless fluid followed, either cerebral or labyrinthine, and the operation was not carried further. The temperature rose to 102 the next day and there was nausea and vomiting. Cerebral trouble was feared, but the temperature slowly went down and the headache and nausea disappeared. The discharge from the ear, while diminishing, continued in spite of cleansing and mild curetting from June 17, 1909, when she left the hospital, until November, 1909. Treatment was continued at my office with occasional curetting of the posterior wall and the Eustachian tube area, from both of which points pus seemed to come. She remained stationary, without much improvement, until in October I began to use the nitrate of silver by the method given, when improvement became rapid, the discharge ceasing by Nov. 1. Examination of her ear a few days ago shows complete healing everywhere, the discharge from the Eustachian tube ceasing after one forcible instillation of the silver. She complained once of considerable discomfort when the silver went into the post-nares. This case also illustrates the fact that even a radical mastoid may not be an absolute success, and that one cannot be sure whether it is or not until many years have elapsed. There were six years between the operations, with a history of no trouble in the interval. Of course I admit the possibility of the first operation not having been sufficiently thorough. As it is sometimes impossible to remove every cell, I think it must be conceded that even apparently thorough operations may possibly require a reoperation at some future date, even some of those that we do at the present day, when the endeavor is made to remove every cell and every vestige of a cell; in spite of this, some cell may be overlooked and reinfection occur.

CASE 4. Miss Z., acute inflammation of the middle ear, mastoid tenderness, ear incised. Patient sent to hospital and ordered cold applications to mastoid, warm syringing to ear, salicylate of soda internally. Acute symptoms all subsided, but the ear kept on discharging. At the end of two weeks the nitrate of silver instillations were begun, and after the third treatment the ear was dry. Of course it may be said that the ear might have become dry in the same time anyway. This is perfectly true, and no attempt is made here to claim that some other method of treatment might not have answered perfectly well.

CASE 5. Mrs. O., occasional suppurative ear for several years, never quite drying up. After four applications of the silver solution complete cessation of the discharge took place. Some hours after the third application there was some pain and I was a little apprehensive whether some injury might not have been done, but the pain soon subsided, and on examining the ear two or three days after it was found to be nearly dry, and after the next application it became completely dry, showing that no harm whatever was done except the discomfort of the pain. This is the only instance in which any patient complained of pain following the application.

Medical Progress.

REPORT OF PROGRESS IN OTOLOGY.

BY HARRIS PEYTON MOSHER, M.D., BOSTON.

(Continued from No. 9, p. 366.)

CIRCUMSCRIBED MENINGO-ENCEPHALITIS.

To the groups of cases classed as circumscribed meningo-encephalitis belong those cases of circumscribed meningitis with great swelling of the cerebellar hemisphere of the posterior cranial fossa in the region of the lateral sinus occurring in connection with infectious thrombophlebitis. It is striking how frequently a circumscribed meningitis is found associated with otitic sinus phlebitis. This may depend upon the fact that the sinus phlebitis is almost always associated with a pachymenigitis externa and not seldom with a pachymeningitis interna.[4]

GENERAL MENINGITIS.

Cases of brain abscess are usually associated with a diffuse meningeal affection. This seldom shows a localization to the diseased side. Alexander reports a case of healed purulent meningitis due to streptococci. This he says is the first reported case which is free from objections. Grademigo was the first, however, to report a healed purulent meningitis (staphylococci). Other cases have been reported by Bertelsmann, Brieger, Grossman and a number of other observers. The organisms usually were diplococci. Once the bacterium coli was found, and in a few instances staphylococci and pneumococci. The healing of streptococcic meningitis has not as yet been proved, but the present case shows that at least in exceptional cases even streptococcic meningitis may get well.

THE PRESSURE OF THE CEREBROSPINAL FLUID.

There may be many variations in the pressure under which the cerebrospinal fluid is discharged. An approximate estimate is sufficient for clinical purposes, so that a special apparatus is not necessary. Under normal pressure the fluid is discharged from the canula in the arc of a circle. With increased pressure it is discharged in the arc of an ellipse, whereas if the pressure is decreased, the fluid leaves the end of the canula at an angle or drops from it. In rare cases a negative result follows lumbar puncture in cases of purulent meningitis where there is thick exudate in the posterior cranial fossa and obstruction to the foramen of Magendi.

[4] Alexander: Monatschr. für Ohrenheilkunde.

In withdrawing the fluid it is important not to contaminate it with blood. This is best avoided, where blood is present, by collecting the fluid in parts in three test tubes. What blood follows the puncture will be collected in the first two tubes, leaving the third tube to collect the fluid in the condition in which it exists in the spinal canal.

INFERENCES TO BE DRAWN FROM CHANGES IN PRESSURE AND COLOR.

Increased evacuation pressure is always a sign of increased intra-meningeal pressure and, therefore, a sign of meningitis. Increased pressure is found chiefly in serous meningitis and in purulent meningitis. Normal pressure is frequently found in tubercular meningitis.

The cerebrospinal fluid should be colorless. White or yellow and cloudy fluid indicates a purulent meningitis. The transparency of the fluid, however, is of more importance than the color. If normally clear fluid contains very small white dots or threads, accompanied by clinical signs of meningitis, meningitis is generally present. In some cases it may be very difficult to distinguish with certainty between true purulent and purulently clouded fluid. It is well to remember, therefore, the fact that in some of the cases determined with certainty a general purulent meningitis may show only a slightly clouded fluid and that in some instances the fluid is entirely clear in the beginning.

As a rule the cerebrospinal fluid in serous meningitis is clear, but Alexander reports a case identical in symptoms with a case which gave clear fluid where the fluid was yellowish-gray and very cloudy.

Alexander repeatedly refers to the importance of finding a cloudy, sterile fluid evacuated under pressure (Brieger, Koerner, Leutert, Wolff, Alexander). This he says may be taken as a characteristic feature of otitic brain abscess. However, cloudy fluid frequently seems to occur only in the manifest stage of brain abscess or immediately before its rupture. Until the last few years this exceedingly important character of the cerebrospinal fluid was unknown. Without going into the question of micro-organisms, the purulent cloudy fluid was regarded as a sign of purulent meningitis, and a contra-indication to an operation, for the reason of not promising success. The autopsy revealed a brain abscess! With a timely diagnosis the patient might have been saved. This point of view has been abandoned. Too much stress cannot be given to the fact that, notwithstanding the great importance of lumbar puncture for diagnosis, and perhaps also for therapeutics, it is of none whatever as an operative indication. As long as the clinical phenomena permit, even a purulent liquor containing micro-organisms should not stop us from operation. Further, it must always be remembered that a markedly purulent cloudy fluid may occur in cases of labyrinthine suppuration or sinus thrombosis.

THE COAGULATION OF THE CEREBROSPINAL FLUID.

If, after the fluid has stood for three to twenty-four hours, a coagulum appears in it, this is an important sign. When the fluid is evacuated clear and under pressure, the appearance of a coagulum is characteristic of serous meningitis.

THE MICROSCOPICAL FINDINGS.

In cases of purulent meningitis, the presence of polynuclear leucocytes and micro-organisms gives a characteristic picture. The microscopical examination, however, is not sufficient evidence upon which to make a judgment as to the virulence of any given case because the bacteria may be dead. Only animal inoculation can give an idea of the virulence of the infection. In the majority of cases, cloudy, gray or yellowish fluid holds bacteria. Even clear fluid, also, may contain micro-organisms. Finally, even in cases of fully developed purulent meningitis, the fluid may sometimes be found clear and sterile. Of especial importance is the result of the lumbar puncture with purulent, inflammatory diseases near the dura, having, however, an extradural course. Such instances are found in cases of purulent sinus phlebitis and large extradural abscess. In these cases more or less numerous polynuclear leucocytes are present in the fluid. Sometimes cloudiness of the fluid depends upon the existence in the fluid of great numbers of polynuclear leucocytes, yet the fluid proves to be sterile.

In cases of meningitis, if an operation is to be done, it must be performed at once. Often it is not justifiable to wait for the results of a microscopical examination. To wait for coagulation to appear, or for the result of inoculation of animals, also, is at times not advisable. Therefore, a judgment must be made from the character of the fluid as it comes from the needle.

THE OPERATION TO BE PERFORMED IN CASES OF MENINGITIS DUE TO EAR DISEASE.

The first end to be accomplished is to remove the suppurative focus from the ear. In acute cases this is done by antrotomy, and in chronic cases by the radical operation. If labyrinthine suppuration exists, a wide opening is to be made into the labyrinth, starting from the vestibule and the promontory of the external semicircular canal. The operation is continued until there is a free flow of fluid. In some cases this means the exposure of the internal auditory canal.

In operating cases of purulent meningitis, the object to be obtained is free drainage of the middle and posterior cranial fossæ, which are chiefly involved in otitic meningitis. In order to accomplish this, first the lower part of the squama and the tegem tympani are removed, and then the sinus and the dura of the posterior cranial fossa in front and behind the sinus are exposed. Both openings are made the size of a dollar and are connected at the level of the tentorium. In cases of labyrinthine suppuration the exposure of the dura of both cranial fossæ

precedes the operation on the labyrinth. Finally, the intradural spaces are drained. This drainage is obtained by a free incision of the dura. Alexander at present recommends four incisions, two in the middle cranial fossa, one between the sinus and the labyrinth and one behind the sinus. Each incision should be about ½ cm. long. By simultaneous puncture of the ventricle the drainage of the cerebrospinal spaces is accomplished.

It is not necessary to make multiple incisions in all cases. If the operator is convinced from clinical symptoms and from the operative findings that meningitis is limited to a region easily accessible for surgical treatment, a single incision in the diseased area may be sufficient. It is recommended, for example, in sinus phlebitis with meningitis, to incise the dura between the sinus and the labyrinth. With purulent labyrinthitis and the clinical phenomena of a meningitis limited to the posterior cranial fossa (marked rigidity of the neck, abductor paralysis), one incision into the dura of the posterior cranial fossa will be sufficient.

The drainage of the intradural spaces is maintained by frequent changes of dressing. The first change may take place on the day of operation. During the first week the dressing is limited to the removal and renewal of the outer layers of the dressing. The lumbar puncture should be repeated after two or three days. At each puncture 20 ccm. of fluid can be withdrawn without risk.

THE PROGNOSIS IN CASES OF MENINGITIS DUE TO DISEASES OF THE EAR.

In arriving at a conclusion as to the prognosis to be given in a case of otitic meningitis, the factors to be considered are:

(1) Whether any micro-organisms are present, and their virulence.

(2) Whether the meningeal changes discovered at the operation show a typical relation to the ear.

In regard to the first point: The virulence of the exciting cause is the important factor. A favorable outcome in cases of purulent otitic meningitis depends upon a low degree of virulence in the infection. Animal experiments alone can settle this point. The mere presence of polynuclear leucocytes indicates meningitis. If bacteria are present as well, a purulent meningitis is present.

In regard to the second point to be borne in mind in making a prognosis: The mode of the development of a meningitis is indicated by the first attack. The more acute and violent the course of the first symptoms, the worse will be the prognosis. A prolonged initial stage and uncertain symptoms make the prognosis of a case more favorable.

Meningitis which is caused directly by a local purulent process in the region of the ear usually from the beginning shows the characteristics of an abscess. It retains this character and remains localized. The more a purulent meningitis represents a remote consequence of ear disease, the more liable it is to become a general meningitis from the beginning. From the practical standpoint the following facts should be borne in mind. With the clinical symptoms of meningitis, the findings during operation will enable the physician to make a probable diagnosis as to the extent of the meningitis. If the inflammatory changes extend from the ear to a circumscribed focus on the dura, and into the dura, there will usually be a partial, encapsulated or circumscribed meningitis. If the purulent changes do not extend from the ear to the dura, there is usually a general meningitis.

At the operation, if the region of the dura about the temporal bone is unaltered and the bone itself shows no necrotic changes, such cases are unfavorable. Finally, that form of purulent meningitis in which the intradural infection starts from multiple inflammatory plaques on the meninges is unfavorable.

A NEW VESTIBULAR SYMPTOM IN DISEASES OF THE CEREBELLUM.[5]

When the Romberg test is applied in cases of left-sided rotary nystagmus of vestibular origin, the patient falls to the right. When the head is turned 90° to the right, the patient falls backward; when turned 90° to the left, he falls forward. This occurs in accordance with a law which Baranay discovered that, in disturbances of equilibrium of the vestibular apparatus, the direction of the fall is influenced by changing the position of the head. Disturbances in equilibrium noted in diseases of the cerebellum differ from those of vestibular origin in that the strict relation between the character and direction of the nystagmus and the direction of the disturbances in equilibrium is lost.

For example, the patient falls to the left with rotary nystagmus, or, as frequently observed, he falls backwards with horizontal or rotary nystagmus. In such cases of disturbed equilibrium, a change in the position of the head does not change the direction of the fall. Cerebellar disturbances in equilibrium have this feature in common with disturbances of equilibrium of hysteric or neurasthenic origin. In two cases of unilateral affection of the cerebellum (clinical observations) Baranay has noted a reaction which may be of great value in the diagnosis of diseases of the cerebellum, especially for localizing right or left-sided site of the affection. In both cases he tested the caloric reaction of the vestibular apparatus (Baranay) and found a typical, well-developed caloric nystagmus on both sides. The disturbances of equilibrium accompanying the caloric nystagmus were, however, atypical. The disturbances of equilibrium of the apparently healthy side could be influenced by changing the position of the head as above described, but on the diseased side equilibrium was not disturbed.

THE DIAGNOSIS OF DISEASE OF THE LABYRINTH.

The subject of labyrinthine nystagmus, when reduced to its lowest terms, is not only very

[5] Dosent Dr. Baranay, Vienna: Laryngoscope, vol. xx, No. 5, May, 1910, p. 560.

pretty, but relatively simple. Looked at in this way, the subject presents itself as follows: Experiments on the semicircular canals in animals have proved that changes in the fluid contained in the canals will cause a change in the position of the eyes. This change is an oscillating movement or nystagmus. The nystagmus takes place in the plane of the canal in which the motion of the fluid is stimulated, and the motion is towards the side of the stimulated canal. With a patient sitting in the upright position, the external horizontal canal is the one in which the motion of the contained fluid is most easily stimulated or changed. The two ways by which the motion of the fluid in the canal is stimulated or changed are, revolving the upright patient about a vertical axis, much as a child spins himself about in order to make himself dizzy, and by injecting into the external auditory canal, for some four or five minutes, hot or cold water. By changing the position of the patient's head all the semicircular canals in succession can be brought under the influence of the turning test. Each pair of semicircular canals can be made horizontal for the time being by changing the position of the head. For instance, by bending the head forward on the chin the two superior vertical canals become horizontal, and by putting the nose in the air, or, better, by having the patient lie on his back, the superior vertical canals again become horizontal. If the head is bent sharply to the right or to the left, so that it lies as nearly as possible on the shoulder, both posterior semicircular canals become horizontal. If one will take the trouble to get a model of the semicircular canals, or will make a rough one out of wire, he will be repaid for his trouble, for immediately he will see how changing the position of the head will in turn make each semicircular canal horizontal. Pictures, owing to the perspective of the drawings, do not make this point clear. Once seen, the point is exceedingly simple.

With the fundamental facts in mind, let us take the next step. The next step is this. When each labyrinth is functioning normally, an equal stimulus is sent from each labyrinth to the eyes. Irritate one labyrinth, as by disease, and the irritated labyrinth sends a greater stimulus to the eyes and pulls the eyes towards the side in which the stimulated or diseased labyrinth is placed. Suppose the disease which at first irritated one labyrinth is sufficient to destroy it. A dead labyrinth ceases to function and sends no stimulus. The well labyrinth, however, still sends its stimulation to the eyes, and as it is unopposed by the dead labyrinth it dominates the situation and causes the eyes to move toward itself or toward the sound side.

(To be continued.)

According to a report made recently by Governor Frear, of the Hawaiian Islands, the birth-rate of Hawaii is decreasing in proportion to the population, while the death-rate is increasing. Last year the deaths numbered sixty-one more than the year before, whereas the births numbered six hundred less. — *Med. Record.*

Reports of Societies.

NEW ENGLAND OTOLOGICAL AND LARYNGOLOGICAL SOCIETY.

A meeting of this society was held at the Boston City Hospital on March 30, 1910.

A. C. Getchell, M.D., *President.*
W. F. Knowles, M.D., *Secretary.*

Dr. J. Payson Clark read a paper entitled

TWO UNUSUAL CASES OF DISEASE OF THE MAXILLARY ANTRUM.[1]

DISCUSSION.

Dr. A. Coolidge: I had seen one or two cases similar to these when Dr. Shaedel's paper came out in 1907. I reported at that time two or three cases in which not only vasomotor symptoms, but other peculiar nervous symptoms were present. They seemed to be relieved when the antrum was washed out. In none of these cases was there any pus in the antrum in which the bacteriological culture was negative. In cases of polypoid degeneration we have all noticed the osteomaxillary is large, almost invariably, if the nose and antrum are full of polypi. We can always get into the antrum with a large-sized probe. In cases of long-continued empyema of the antrum without polypi, the osteoma becomes large, so it does not readily probe. It has always seemed as though the large osteoma was the result of the disease. Dr. Shaedel's idea was that it was the other way; that it was on account of the large-sized osteoma that the antrum became irritated, and, secondly, that we had vasomotor disturbances. I do not think he proved his case at all, but certainly, in a certain number of cases, there is a connection between the secretion in the antrum and vasomotor disturbances.

Within a month I have seen a case in which the antrum contained a mass of thick mucus which dropped into the basin when the antrum was being washed out. The case had vasomotor symptoms. It was pale and swollen. It evidently and probably was proved to be the case that the irritation in the nose was due to a sarcoma in the nose, which was then hidden and unsuspected. That rather looks as though this thick mucus was simply a secretion from vasomotor rhinitis in certain conditions. I mean that the thick mucus we sometimes find in the nasal cavity becomes impacted there and forms this tenacious mass. On the other hand, there is something about this we have not yet discovered, because, in a certain number of cases, the mere washing out of the antrum will mysteriously relieve indefinite vasomotor symptoms. I think it is a subject it is well to bear in mind and investigate as these cases arise, because I think there is something which is still hidden which we do not fathom entirely.

Dr. F. C. Cobb: I think these cases are interesting from the causative standpoint, to me particularly. It seems to me that the only evidence on which the assumption can arise that the mucus in the antrum has irritated the rest of the tract is that it has improved the rest of the nose, occasionally, washing it out. Of course we know that washing sometimes results in an improvement of the nose because the washing is pretty thorough. The water comes down from the upper meatus and clears the nose out pretty thoroughly. That does not seem to have always taken place. In one case after each washing there was less and less mucus until the thing improved; then the patient would go away to New York or somewhere and come back with a cold

[1] See Journal, p. 395.

and more mucus. Why are not these cases, then, an inflammatory condition or a vasomotor condition of the nose, accompanied by a vasomotor condition of the antrum, or inflammatory condition, if you like, or a mixture of the two? Because we know the natural mucous membrane is thickened and that the prognosis in transillumination is due to thickening in the antrum, not the secretion in it. Is not the antrum part of the whole inflammatory condition in the nose, in the cases cited, and the amount of mucus simply the mucus secreted by the antrum, and is the antrum, therefore, the cause of the general vasomotor rhinitis? It seems to me that this is hardly probable. The antrum may not be a factor, but a part of the whole general inflammatory condition.

DR. GEORGE L. RICHARDS: I knew Dr. Shaedel very well. Dr. Coolidge spoke of his paper in 1907; I do not know whether Dr. Coolidge saw the paper published after Dr. Shaedel's death. There is one thing in regard to his work that Dr. Cobb's work calls to my mind. Dr. Shaedel claimed that he cured a great many cases by the application of a solution into the antrum which would seem to have proved therapeutically that the curative agent was introduced into the antrum.

DR. J. P. CLARK: I have nothing to say in concluding except in answer to what Dr. Cobb said. In the first place, there was no thick mucus in the nose at any time except what came out of the antrum; the secretion of the nose was watery. In the first place, I used washes in the nose for some time, only to make the symptoms worse. It was not until I washed out the antrum that the nose got better.

Then as regards — Dr. Cobb spoke of these cases recurring. Perhaps I did not make clear that the intervals were very long. In one case the patient did not have any trouble for four years, so it could not have been a constant condition in the nose all that time.

Book Reviews.

Surgery: Its Principles and Practise. Vol. V. Edited by W. W. KEEN, M.D., LL.D., Hon. F.R.C.S., England and Edinburgh, Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Philadelphia: W. B. Saunders Company. 1910.

The fifth and final volume of Keen's Surgery is composed of seventeen monographs, with a total of 1,200 pages. As in the previous volumes, each monograph is called a chapter and the first two chapters make one half of the entire volume, the others varying from 13 to 90 pages. The articles are: "Surgery of the Vascular System," Rudolph Matas, M.D., 334 pages. "Surgery of the Female Genito-Urinary Organs," E. E. Montgomery, M.D.; John M. Fisher, M.D.; P. Brooks Bland, M.D., 236 pages. "Surgical Technic," John H. Gibbon, M.D., 68 pages. "Ligation of Arteries in Continuity," Warren Stone Bickham, M.D., 77 pages. "Operations on Bones and Joints," James Peter Warbasse, M.D., 58 pages. "Amputations," Warren Stone Bickham, M.D., 89 pages. "Plastic or Reconstructive Surgery," John B. Roberts, M.D., 36 pages. "Surgery of Accidents," Walter L. Estes, M.D., 33 pages. "Surgery of the Parathyroid Bodies," Charles H. Mayo, M.D., 16 pages. "The Intracranial Surgery of the Fifth and the Eighth Nerves," Charles H. Frazier, M.D., 36 pages. "General Anesthesia and Anesthetics," Hobart Amory Hare, M.D., 45 pages. "Local and Subarachnoid Anesthesia," Karl G. Lennander, M.D., and Fredrik Zachrisson, M.D., 56 pages. "The Surgery of the Infectious Diseases," George E. Armstrong, M.D., 42 pages. "The Use of the X-Ray and Radium in Surgery," Ernest Amory Codman, M.D., 37 pages. "The Legal Relations of the Surgeon," Hampton L. Carson, Esq.; 18 pages. "The Laboratory as an Aid to Surgical Technic and Surgical Diagnosis," Wm. McLete Caplin, M.D., 13 pages. "The Surgical Organization of a Hospital," Albert J. Ochsner, M.D., 24 pages.

Matas' article upon the Vascular System would make a fair-sized volume itself; it is exhaustive and goes into minute details; its bibliography is extensive and is given in sections, each following one of the many divisions into which this admirable monograph is divided. The writers upon the surgical aspects of gynecology have made their chapter about one third shorter than the one preceding (Matas'), an unusual and praiseworthy proceeding; all that is essential to the subject is concisely presented; we miss a little some illustrations which would probably have been included had space permitted; it is to be commended for its sound judgment and moderate conservatism.

Gibbon has written the best chapter on technic that we have read; it is entirely satisfactory. The two chapters by Bickham maintain the high standard of his larger textbooks both in matter, manner and illustration; exceptionally good are the pictures of cross sections of the extremities; much the same sort of praise must be given to Warbasse for the treatment of bone and joint operations.

Roberts writes most interestingly upon plastics, and has many excellent illustrations, besides a long bibliography. Estes, on accident surgery, has written one of the best articles in the book — a statement which may be immediately repeated in relation to Mayo's short chapter on the parathyroids. Frazier writes admirably upon the fifth and eighth nerves, a chapter which might have been well placed in Vol. III, which contained the surgery of the head. Anesthesia is very properly given 100 pages; general anesthetics are covered in Dr. Hare's well-known and efficient manner; local anesthesia was necessarily divided into a chapter excluding spinal anesthesia, and another devoted to that subject, owing to the unfortunate death of Lennander, before the latter article was finished; his assistant, Zachrisson, has completed the work. Taken together, the subject is most satisfactorily treated, and the enormous field of this growing method is convincingly demonstrated. Codman has, in our opinion, produced the best article upon the use of the x-ray that has yet appeared in print.

This volume completes what may be literally described by the hackneyed phrase, "a magnificent work." Dr. Keen points out that 5,500 pages have taken the place of the 4,000 of the original plan, that the work has grown one quarter in the making. It is the common history

of textbooks, and one greatly to be deplored. While convinced that this is the best system of surgery that has appeared in America, we are equally convinced that it would have been twice as effective if it were half the size. Somewhere between 1,000 and 6,000 pages must the ideal textbook be found. We are confronted, however, not so much with the ideal as the real, and if we must have a system, let us have this of Dr. Keen.

American Practice of Surgery. A Complete System of the Science and Art of Surgery. By representative surgeons of the United States and Canada. Editors: Joseph D. Bryant M.D., LL.D., and Albert H. Buck, M.D., of New York City. Complete in eight volumes. Profusely illustrated. Volume VII. New York: William Wood & Co. 1910.

This Volume VII will probably appeal to the general surgeon more than have any of its predecessors. It is a truly interesting collection of important monographs by well-known contributors to surgical literature.

Charles H. Peck, of New York City, and C. A. Porter and William C. Quinby, of Boston, contribute the first two essays, — Peck on the Surgery of the Bony Pelvis and Porter and Quinby on various minor diseases of the extremities, diseases which have not been discussed in previous articles in this series. Peck's essay is a good one, and is modern. He deals especially, and in an interesting fashion, with such topics as sacro-iliac disease and pelvic deformities, as well as the more frequent ailments, — fractures, pilonidal sinus, and the various tumors and inflammations of the region. Porter and Quinby discuss, among other topics, such interesting lesions as x-ray burns and the malignant changes which may complicate them, the various forms of bursitis which recently we have come to understand and several familiar but little discussed topics, such as ingrowing toe-nail and paronychia. The chapter is interesting because it deals with every-day subjects. It is fairly well written.

J. D. Griffith, of Kansas City, writes on Surgical Diseases of the Abdominal Wall. Every system of surgery contains such a chapter, and the writer of it must groan in its production. Griffith has done extremely well with a most uninteresting but necessary topic.

M. L. Harris, of Chicago, discusses in his usual brilliant fashion the Diagnosis of Abdominal Tumors, and while his writing covers but eight pages, it is extremely well worth reading.

William McD. Mastin, of Mobile, follows with a chapter on Abdominal Section. The writing is rather fragmentary, but the chapter contains a good deal of useful routine information.

R. G. LeConte and F. T. Stewart, of Philadelphia, follow with an extremely readable and modern chapter on the Pericardium, Heart and Blood-Vessels. We doubt if they add any special notes of importance to the large literature of the subject, but their collection of facts, both historical and critical, is probably the best yet made. The casual reader, especially, will be interested in their descriptions of the suture of blood-vessels and the modern method of treating aneurism. It is too bad that all writers on aneurism have to fall back on the rather crude sketches which Matas first supplied to the *Annals of Surgery* eight years ago.

A. J. Ochsner, of Chicago, contributes one of the best chapters in the book, that on the Stomach and Esophagus. While the writing is rather discursive and disjointed, the subject-matter is full and satisfactory. The great experience of the writer is well illustrated by the admirable sketches in the text.

To J. C. Reeve, Jr., of Dayton, Ohio, is assigned the rather difficult subject of Diseases of the Diaphragm and Subphrenic Abscess. He has acquitted himself admirably and has made of his writing a truly interesting and readable chapter.

The lamented Andrew J. McCosh, of New York, has left behind for publication in this volume two admirable essays on the Surgical Treatment of General Peritonitis and on Diseases of the Vermiform Appendix. McCosh was a satisfactory writer, as he was a painstaking and thorough clinician. Both of these chapters bear witness to his experience, resourcefulness and unusual skill, as well as to his fairness of mind and maturity of judgment. The chapter on appendicitis, especially, may almost be ranked as a classic.

Nathan Jacobson, of Syracuse, contributes an excellent article on Tuberculous Peritonitis, excellent and final so far as our present knowledge reaches.

E. Wyllys Andrews, of Chicago, always interesting in what he has to say, writes the chapter on Abdominal Hernia. His illustrations, especially, are of unusual value, more particularly the original sketches of his own well-known operation for inguinal hernia. The writing is well balanced and the descriptions good.

C. W. Oviatt, of Oshkosh, has not often of late been a contributor to surgical literature, but his present chapter on the Intestines, Omentum and Mesentery is thoroughly worth reading. His illustrations also are satisfactory, and his advice regarding methods of diagnosis of intra-abdominal lesions, and the surgical treatment, especially, of intestinal disorders, is sound and illuminating.

Perhaps the most interesting chapter of the book to general surgeons is the last chapter, by J. P. Tuttle, of New York, and S. T. Earle, of Baltimore. They write on Surgical Diseases of the Anus and Rectum, and their writing is unusually forceful and instructive, while their illustrations are particularly satisfactory. We have mentioned several times this subject of illustrations, because illustrations enter largely into the proper composition of modern surgical writings.

We trust sincerely that in the next volume a proper general index to the whole edition may be supplied.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 8, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

RESULT OF THE FOURTH OF JULY PRECAUTIONS.

IN the current number of the *Journal of the American Medical Association* are presented the statistics of injuries during the Fourth of July celebration of 1910. This is the eighth consecutive year that this journal has undertaken this laborious task, which certainly is bearing fruit in calling attention to the extent of the accidents and to their alteration for the better under certain legal restrictions. It appears from these figures that there were this year only seventy-two cases of tetanus, as contrasted with one hundred and fifty last year. In connection with this it appears that the number of blank cartridge injuries shows the astonishing decrease from twelve hundred and twenty-five in 1909 to only four hundred and fifty in 1910. Injuries from the use of blank cartridges are most frequently the cause of tetanus, hence it is evident that the greater precautions which have been taken and the decrease in the number of cases of tetanus is not a mere coincidence. It appears that in the seventy-two cases of tetanus, antitoxin was employed in twenty-five instances, but in only one case before the active symptoms had supervened. Of the cases occurring this year, ninety-three per cent ended fatally, a somewhat larger percentage than for the three or four previous years. The reason for this is apparently not stated, unless it may be attributed to the imperfect and incomplete administration of antitoxin. Sixty-four persons were killed by the use of fire works of various sorts, which, added to the sixty-seven deaths from tetanus, bring the total mortality up to one hundred and thirty-one, a most gratifying decrease from immediately preceding years. In fact, this is the lowest number of deaths since 1903. There were 2,792 injuries incurred which were not fatal, but this again is but little more than half the total of last year.

Among the implements causing mutilating wounds, the giant fire cracker with a short fuse easily holds first place. The astonishing number of 1,050 injuries were due to the giant fire cracker alone. Naturally fire arms and other less dangerous means of celebration constitute a cause of numerous injuries, but the number is small considering the extent to which they are used.

The excellent showing made this year is unquestionably due to an awakened public spirit as well as to definite restrictive legislation in various parts of the country. For example, Trenton, N. J., had no injuries, due undoubtedly to a prohibitive ordinance passed last year; Cleveland had but one injury, and in that city also a prohibitory ordinance is in force. The same is true of Washington and Baltimore. Our contemporary is inclined to think that the responsibility for the majority of the Fourth of July injuries rests with city governments. If this be true, the means of still further reducing the mortality and lessening the number of injured is self-evident. There is no reason to suppose that if the authorities will take sufficient interest in the matter, means of enjoyment fully as keen and far safer may be devised for the amusement of the public on Independence Day. Recent events have demonstrated that the tendency is strong in this direction and that before many years have passed the danger-dealing forms of amusement may be limited only to responsible persons, and the people at large find means of expressing their patriotism in less harmful and really more enjoyable ways. In the meantime we trust the *Journal of the American Medical Association* will continue its statistical inquiries, which will do more than any other one method toward determining the exact situation and the exact problem to be met by restrictive or prohibitory legislation.

MEDICAL ENROLLMENT.

THE enrollment of medical students will be watched this year with even greater interest than heretofore owing to the possible effect of Mr. Abraham Flexner's investigations and conclusions regarding the status of various medical schools throughout the country. For some years past there has been a distinct tendency toward an elevation of standard, which among other and more subtle causes has no doubt led to a certain

diminution in the number of men undertaking the medical profession. Exactly what effect Mr. Flexner's careful and outspoken criticism of existing conditions will have is as yet purely problematic. It is possible and certainly to be hoped that one result will be a more generous enrollment of students at our better high standard schools and a diminution in the number attending those of lower standard. It is not probable that the schools which Flexner considers unworthy of existence will forthwith close their doors unless public opinion as represented by student enrollment forces them to this measure. On the other hand, it is to be hoped that the strictures which have been brought against methods still in vogue in this country may have a salutary effect in forcing home the lesson that if a school is ultimately to maintain itself with credit and with usefulness to the community it must raise its standards from the low level with which many institutions have hitherto been contented. Flexner has undoubtedly shown by actual figures that the United States is very decidedly overstocked with physicians. He has also shown that this overstocking is with physicians of poor education rather than with those who are likely to advance the science and art of medicine. These facts as presented by him cannot be evaded and we have confidence enough in the awakened public spirit of the country to believe that lower grade medical schools must accept the fact, unwelcome as it may be, and either leave the education of prospective physicians entirely to other and better equipped institutions, or raise their own standards. In either case benefit will result and the tendency be established for persons of poor training to seek other means of livelihood than medicine. It may in general be said that our best medical schools have not enough students, a matter to which we have continually referred in the past years. That this situation may gradually change for the better is perhaps possible, but we believe improbable under existing conditions. However this may be, we shall await with extreme interest any indication of improvement in the general situation as shown by the forthcoming opening of the schools.

WORKMEN'S COMPENSATION ACT.

On Sept. 1 the new Workmen's Compensation Act, passed at the last session of the New York Legislature, went into force. It is, it will be remembered, based on the principle that the burden for industrial accidents not due to the wilful misconduct of the employee should be borne by the industry, instead of, as is now the case in the majority of instances, by the man injured or his family. The changes effected by the bill fall into two classes. The first amends the general employers' liability law so as to give the employee certain advantages. The second provides a scale of compensation, optional in the ordinary trades, but mandatory in certain occupations (designated under eight heads), which are recognized as especially dangerous. In these, it is stated, extraordinary risks to the life and limb of workmen engaged therein are inherent, necessary or substantially unavoidable. Consequently the law provides the following schedule of compensation: (1) In case of death, four years' wages, not to exceed $3,000; (2) in case of total incapacity for a period not to exceed eight years, 50% of the workman's average weekly earnings; (3) in case of partial disability for a period not to exceed eight years, 50% of the difference between his average weekly earnings before and after the accident.

While the employer is bound to pay this rate of compensation in these "especially dangerous" kinds of work, and cannot plead the contributory negligence of the workman in his defense, the employee is not obliged to accept such compensation. He may waive his rights under the mandatory clauses, and sue the employer under the general employers' liability act; but once he has decided to do this, he cannot demand the statutory scale of compensation. Some doubt has been expressed as to the constitutionality of these mandatory provisions, on the ground that they constitute the taking of property "without due process of law." On the other hand, the supporters of the new measure claim that the obligatory clauses are merely an exercise of the police power of the state. It is recognized, however, that this constitutional point will have to be taken to the highest courts for settlement. The same scale of compensation may be applied to other than the "especially dangerous" occupations by the mutual consent of the employer and the employee. If this agreement is entered into, the employee waives all his future rights under the liability act, and is limited to the compensation laid down in the schedule, unless there has been serious or wilful misconduct on the part of the employer. In the same way, the employer cannot escape paying the fixed rate of compensation unless he can show serious and wilful misconduct on the part of the employee. It is not claimed that

this law is a final solution of the problem concerned, but merely the inauguration by the state of a new policy, which, it is hoped, will eventually lead to its satisfactory settlement.

MEDICAL NOTES.

RADIUM. — It is stated from Paris that Madame Curie has announced the discovery of pure radium. Up to this time radium has been known only in the form of salts.

CHOLERA. — In view of the presence of Asiatic cholera in Russia, Italy and Germany, Health Officer Doty of New York, is taking precautions with all incoming vessels. Not only the steerage, but the cabin passengers are subjected to a thorough examination. All passengers who show suspicious symptoms will be transferred to Hoffman Island for observation. The steamships will be disinfected before being allowed to come up to the city. On Sept. 2 the Cunard liner *Lusitania* was held in quarantine for thirteen hours because of the illness of a Roumanian steerage passenger. Some of Dr. Doty's staff worked all night in the laboratory to make the required bacteriological tests, but the result showed that the man was suffering from ordinary cholera morbus and not Asiatic cholera. One result of the delay of the *Lusitania* was that Dr. Henry, surveyor of the port, has recommended to Collector Loeb that no steamships be permitted to dock at night until the disappearance of cholera in Europe.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Sept. 6, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 26, scarlatina 18, typhoid fever 26, measles 12, smallpox 0, tuberculosis 56.

The death-rate of the reported deaths for the week ending Sept. 6, 1910, was 15.56.

BOSTON MORTALITY STATISTICS. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Sept. 3, 1910, was 188, against 185 the corresponding week of last year, showing an increase of 3 deaths and making the death-rate for the week 15.56. Of this number 104 were males and 84 were females; 34 were white and 8 colored; 126 were born in the United States, 59 in foreign countries and 3 unknown; 34 were of American parentage, 129 of foreign parentage and 25 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 32 cases and 2 deaths; scarlatina, 13 cases and 1 death; typhoid fever, 30 cases and 2 deaths; measles, 12 cases and 2 deaths; tuberculosis, 67 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 9, whooping cough 2, heart disease 18, bronchitis 4. There were 11 deaths from violent causes. The number of children who died under one year was 54; the number under five years, 71. The number of persons who died over sixty years of age was 39. The deaths in public institutions were 88. Cerebrospinal meningitis, 1 case. Anterior poliomyelitis, 4 cases and 1 death.

Of the above infectious diseases the following were non-residents: Anterior poliomyelitis, 1 case. Cerebrospinal meningitis, 1 case. Consumption, 3 cases and 1 death. Diphtheria, 4 cases. Scarlet fever, 1 case.

Deducting deaths of non-residents, the total is 169 and the death-rate is then 13.99.

DONATION OF BED TO FLOATING HOSPITAL. — Nathan H. Reed, of Somerville, Mass., has endowed a bed on the Floating Hospital in memory of Mrs. Clara B. Reed, who formerly was much interested in the work of this charity.

OPENING OF SCHOOLS IN FALL RIVER DELAYED BY POLIOMYELITIS. — Owing to the prevalence of poliomyelitis in Fall River, Mass., a recommendation has been made by the Board of Health to defer the opening of the public schools to Sept. 19, two weeks later than the usual date.

MEETING OF HAY FEVER ASSOCIATION. — The annual meeting of the United States Hay Fever Association, which ended its sessions Aug. 31, showed an increased membership and greater enthusiasm than heretofore for the work which the association has set itself to do. Methods of combating the affection were reported.

TYPHOID FEVER IN GLOUCESTER, MASS. — It is reported that twenty-five or more cases of typhoid fever have appeared in the Portuguese section of Gloucester, Mass.

NEW YORK.

POPULATION AND THE BUDGET. — While the increase in the population of the city of New York in the last ten years has amounted to 39%, the

increase in the city's budget has been much greater than this. Thus, the annual appropriation for the Health Department, on account of the growth of medical knowledge and the pressure of modern conditions, has had to be increased to about 124%. In 1900 this was $1,055,515, and in 1910, $2,737,723. Yet, in view of the demands upon the department, by reason of its campaign against tuberculosis and of the more strict supervision over the milk supply and child hygiene, as well as the laboratory work in tuberculosis, diphtheria, tetanus, rabies and other diseases, this large increase in the annual appropriation is declared by those familiar with the situation to be entirely inadequate for the most efficient carrying on of the work of the department. Of course, an important element in the increase has been the greatly augmented number of officials required.

Medical Officials of the Health Department. — In view of the fact that the Bureau of Municipal Research has addressed a communication to the 1911 Budget Committees of the Academy of Medicine and the County Medical Society, in which it is suggested that there might be less preventable illness and mortality in the city if the medical officials of the Health Department were expected to give their time exclusively to the work of the department, Dr. L. Emmett Holt has sent a letter to the bureau, in which he says that the question has two distinct sides to be considered: (1) The needs of the department, and (2) the needs of the physicians themselves. "In point of view of efficiency there is no doubt in my mind that it could be increased if a physician's time were not divided between his private practice and his public service. But how about the physicians themselves? There is no inducement whatever for the best medical men, or even fairly good medical men, to enter the service of the city with a view to continuance." In citing as an instance the position of Health Commissioner, Dr. Holt says that at the end of his four years' service such a one finds his position gone, his practice helplessly scattered and perhaps himself practically out of everything medical. To build up a new practice is almost an impossibility at the probable age of a retired health commissioner. The department, the letter continues, could not hold other specially qualified men for a month if they were obliged to devote their entire time to department business. Unless the city is prepared to pay department heads $10,000 and make their positions permanent, and to pay $5,000 and $3,000 for subordinate positions, it cannot hope or expect to retain men of even moderate ability. Supposing for a moment the subordinate positions of inspector, diagnostician or even attending physician to special hospitals were made permanent, and paid salaries of from $2,000 to $5,000, the places would naturally come under civil service rules, and a man once in could not be removed except for cause which the courts would sustain. Incompetence and inefficiency are very difficult things to prove. I feel sure that a much worse state of things than at present exists would be the result of such a system. The city cannot hope, under any conditions which seem even remotely probable, to secure the full time of any considerable number of men for its medical service. It is greatly in need of a few men of this character, whose tenure of office should be permanent, not depending upon a civil service examination for their appointment, or the success of a political party to keep them in office. Such a group of from three to five in number could organize the department and make efficient the work of the corps of physicians who compose the ranks. Such latter class will certainly be drawn from able young men, who hold their positions for a few years until somewhat established in practice, but who have enthusiasm and energy, or from unsuccessful older men who have tried but failed to support themselves by practice alone. The latter might be willing to give all their time, but their service will be much less advantageous to the city than that of the younger group referred to.

12. *RANDALL, B. A. *How Far is Heredity a Cause of Aural Disease?*

2. Elliott's article is an eminently rational consideration of the significance and management of arterial hypertension. He deals chiefly with those cases, the great majority where this condition is present, of arteriosclerosis and chronic nephritis. The chief cause of hypertension he considers to be toxic influences, abnormally retained in kidney disease, originating probably in the alimentary tract. The brunt of the disturbance is borne by the heart, which first, for a time, hypertrophies, but later dilates and becomes unequal to its work. The blood vessels also, notably the cerebral arteries, may give way under the increased strain. In treatment, the chief indication is detoxication. To this end he advises a diet of restricted amount and low proteid content, with, during hypertensive crises, periods of starvation with restriction of fluids, or a diet solely of bread and fruit. Salt is to be avoided in proportion to the severity of the case. Sweats may be of benefit. Daily purgation by a saline laxative is, perhaps, the best single measure. With regard to the use of vasodilator drugs, while in general he accepts the views of Krehl and of Janeway that high blood pressure is a compensatory process which it is dangerous to directly combat, still he maintains that in certain cases the cautious use of sodium nitrite may afford relief of symptoms; the coincident use of iodide may increase this effect. It is well to test the efficiency of the heart by Gräupner's method, following the course of blood pressure after measured exercise, weak hearts failing to show the normal increase, but giving rather a decline in pressure. If this test shows a tendency to ventricular weakness, the nitrites should not be used, but rather rest and digitalis.

3. Schwartz and Ottenberg discuss the nature of hemorrhagic disease of the newborn in connection with two cases. Coagulation of blood is believed to be due to the union of fibrinogen with fibrin-ferment, which is made up of three constituents, kinase, calcium and prothrombin, all of which are essential to the process. It is further believed that an antiferment exists which may at times prevent coagulation. Studies of the blood in these cases showed that the failure of the blood to coagulate was due to absence of thrombokinase. Transfusion is considered to be the only efficient therapeutic measure, and even this may fail if the cause of the disease, usually bacterial infection, but sometimes syphilis alone, continues.

6. Alvarez describes disturbances of the thyroid as extremely common in northern Mexico, and as varied in their manifestations. Goiter is endemic. Abnormalities of thyroid function are encountered, varying from myxedema to exophthalmic goiter, with intermediate "*formes frustes*" and unclassified states that are gradually becoming recognized as connected with the thyroid. Asthenia with obesity, relieved by thyroid treatment, is described as a common occurrence. Rheumatoid pains are suspected to be due to hypothyroidism. Attacks resembling hysteria, with convulsions, substernal pain and numbness of extremities, compared by Alvarez to those occurring in Halsted's case after complete thyroidectomy, are a frequent complaint.

7. Marchildon reports two cases at autopsy, one showing acute spermatocystitis and the other acute prostatitis, both occurring in the course of typhoid fever and both with typhoid bacilli in the local lesions. Marchildon suggests that such infections may play a part in the continued presence of typhoid bacilli in the urine of typhoid "carriers."

10. Kaplan shows that the Wassermann reaction is not specific for syphilis and believes that neither the Wassermann nor the Noguchi reaction alone is sufficiently accurate for diagnosis, but that when both are positive there is reason strongly to suspect syphilis provided scarlet fever, leprosy, trypanosomiasis and scleroderma are excluded, and provided the serum does not contain bile. A negative reaction may be the result of antisyphilitic treatment, but is no indication for cessation of treatment.

12. Randall believes that the supposed heredity of aural disease cannot be accepted as more than a predisposition, yet this is enough to demand special attention to environment and habits, with early removal of adenoids or other nasal obstructions that cause mouth breathing. [F. W. P.]

1. From the fact that he has been able to collect fifty-two cases in his personal practice and from the hospital services of his colleagues during the past six years, Thompson maintains that trichinosis is much more common than is usually supposed, and frequently fails of recognition. Its symptoms and course may be summarized as follows: Onset acute with chills, muscular pains, vomiting, frontal headache, prostration and fever; incubation period, nine days to three weeks; diarrhea not constant, tympanitis frequent; erythema of face and neck frequent, herpes labialis and a macular rash on the abdomen occasionally seen; muscle tenderness usually general and severe, especially in arms, calves of legs, thighs and diaphragm; pain in the eyes frequent, often with corneal hemorrhages; edema of lids variable; edema of ankles and about other joints common; respiration often rapid and shallow, but without discomfort; urine sometimes dark, diazo-reaction frequent; white count usually moderately increased; *eosinophilia invariably present*, 30 to 80%. It resembles most closely typhoid fever, polymyositis, septicemia, aestivo-autumnal malaria, and occasionally rheumatism. The temperature rises acutely, but falls by lysis after from a few days to several weeks; there may be a relapse. Of the 52 cases, 2 died, one from the disease itself, the other from pneumonia. The muscle was examined in 34 cases; in 29 trichinæ were found, and in the remaining 5 an acute myositis.

2. Albert reports a small epidemic of trichinosis traced to the eating of boiled ham. According to reports from a number of packing houses, the temperature and duration of cooking of boiled ham is variable and may sometimes be insufficient; the amount of cooking necessary is not adequately determined. The eosinophilia is emphasized as of great diagnostic value.

3. Hartwell and Cecil call attention to the subject of intestinal diverticula, which, although they have long been recognized, have only recently been connected with acute inflammatory conditions. Diverticula are pouch-like outgrowths from the intestinal wall, varying in size from a buckshot to a hen's egg, often multiple, situated most frequently in the descending colon or sigmoid. They are of common occurrence, different observers having found them in from 15 to 30% of all cadavers. Their clinical importance lies in their liability to be the site of inflammatory changes in every way comparable to those which occur in the appendix. They may become inflamed without perforation, or may perforate, causing abscess or general peritonitis; the inflammation may be of a chronic mild type, which may lead to great thickening; carcinoma may develop.

4. Phillips describes the skin lesions other than rose-spots which occurred in a series of 1,230 cases of typhoid

fever. Herpes occurred in 12 cases; urticaria in 21; desquamation in 83; erythema, sometimes resembling scarlet fever, in 7; purpura in 6; a pemphigoid eruption in 4; also erysipelas in 2, bedsores in 12, furunculosis in 45, carbuncle in 2, onychia in 5, and other septic conditions of the skin. There was one instance of patellar striæ, a somewhat rare phenomenon, which was probably due to rapid growth during the disease.

6. Schloss reports four cases of acute articular rheumatism with which were associated purpura, urticaria, angioneurotic edema, erythema simplex, erythema nodosum, erythema exudativum and erythema multiforme.

7. Barton calls attention to the disease of acquired hemolytic ictero-anemia first described by Widal in 1907, and reports a case, the eighth that has been published. The disease is characterized by jaundice and anemia, with enlarged spleen, without clay-colored stools or bile in the urine. A leucocytosis is usually present, otherwise the smear resembles that of pernicious anemia, but on testing the behavior of washed red corpuscles in hypotonic salt solutions they are found to be abnormally fragile and susceptible to hemolysis.

8. Simonds publishes a careful summary of reported studies of typhoid bacilli carriers, but without original observations.

9. Stern considers the question of what importance previous acute infectious diseases may have in the production of chronic nephritis. Of 200 cases of chronic nephritis, 192 had at some period had one or more acute infectious diseases, accompanied in at least 121, and perhaps in 56 or 58 more, by acute renal involvement. He concludes that acute nephritis prepares the way more than is generally realized for chronic nephritis, either parenchymatous or interstitial or amyloid, even though a direct transition cannot be traced.

11. Young advocates aspiration by means of a hypodermic syringe for the diagnosis of suspected tuberculous abscesses, particularly in connection with diseases of joints. [F. W. P.]

4. FOSTER, N. B. *A Study of the Nitrogen and Sulphur Metabolism in Morbus Cæruleus.*
5. *LYON, I. P. *Adiposis and Lipomatosis Considered in Reference to their Constitutional Relations and Symptomatology.*

1. This article gives some further observations by Craig upon the subject of recurrent diarrhea due to parameba hominis. He has found the parasite in six Filipinos and three American soldiers, and has worked out its life cycle. He suggests that some of the cases of chronic diarrhea, especially in the Southern states, may be due to this protozoan.

3. Fabyan reports three cases in which tubercle bacilli of the bovine type were isolated from the lesions. All cases had been infected through the intestine. One showed tuberculous lymphadenitis (mesenteric); another, tuberculosis of the intestines and mesenteric lymph nodes, and of lungs, spleen, liver and peritoneum; the third, tuberculous mesenteric lymphadenitis and tuberculous meningitis.

5. Lyon, in his article on adiposis and lipomatosis, describes twenty cases, some of which are shown in interesting photographs. He groups the cases according to their clinical findings, and discusses each class at some length. The cause of these conditions, he says, is unknown, but he believes they are due most probably to the derangement of some internal secretion. [G. G. S.]

5. Weil reports the results of his examination of a number of ascitic fluids, among which was the fluid from the case of cancerous ascites with which Dr. Hodenpyl produced retrograde changes in the cancerous organs of some patients into whom he injected the fluid. Weil tested these fluids for their lytic power upon blood and tissues, for their precipitin and agglutinin reactions, and for their antitryptic activity. There was no indication which he could find of "the existence of any specific character such as would serve to differentiate with certainty fluids derived from cancerous individuals from those of another origin."

10. Gurd reports a study of twenty cases of salpingitis. From the fact that 30% were positively gonorrheal, 25% almost certainly so, and 20% more probably so, he concludes that the gorrorrheal origin of salpingitis is more frequent than we suppose. By scraping the wall of the lumen, gonococci can frequently be cultivated. In the histological picture, the plasma cell is greatly in preponderance. [G. G. S.]

5. MEIROWSKY AND FRANKENSTEIN. *Amenorrhea and Tertiary Syphilis.*
6. KUHN, F. *Air Compressor in the Hospital.*

1. Siegert presents a good article on the subject of measles. He presents first the different ideas and his own in regard to what period of the disease is most contagious. The unanimity of opinion is that the danger lies either before the eruption or early during it. He then takes up the different points in making an early diagnosis and the different ideas in regard to treatment. He is opposed to hospital treatment if good home treatment is possible on account of the liability to contract other infections. The paper is a good review of the situation without adding much to the subject.

2. Hirsch reports a case of temporary blindness coming on two and a half hours after concussion due to being knocked down by an automobile, which cleared up entirely in three days. After recovery there was no remembrance of the injury or blindness, although before and following this period facts are remembered. He takes up a theoretical discussion of the possibilities in regard to the cause. [C. F., JR.]

24. Michelsson's article on spinal anesthesia is a critical review of 400 cases treated by this method at the clinic of Von Bergmann at Riga, between May, 1906, and February, 1909. He precedes this review by a discussion of the technic of and indications for spinal anesthesia. Stovain is his choice rather than tropacocain or novocain, and the preparation of stovain which he uses is that of Billon. This comes in sealed ampullæ, each containing 2 ccm. of a 4% (equal to 0.08 gm.) solution of stovain with a slight addition of common salt (0.11%) and boric acid epirennin (0.00013%). This solution is isotonic with spinal fluid. Stovain is only one half to one third as poisonous as cocaine, but has an affinity for motor nerves and is slightly irritating to the tissues. It remains for about seven hours in the spinal fluid.

Michelsson favors a preliminary dose of scopolamine and morphine; he then inserts his needle containing an obturator through the skin in the median line, between the spinous processes of the second and third lumbar vertebræ. After the needle has penetrated a distance of 1 cm., the obturator is withdrawn and the hollow needle pushed in until spinal fluid is reached. The amount of this withdrawn depends upon the force with which it is expelled. Michelsson withdraws from 1 to 3 ccm. before injecting 1.4 ccm. of the solution.

After the injection of the solution with a syringe, and the withdrawal of the needle, the patient lies horizontal, with head and shoulders slightly raised, for from five to ten minutes. Formerly the pelvis was raised, but it is to this maneuver that Michelsson ascribes most of their untoward results.

In the selection of cases for this method of anesthesia, the old, feeble and cachectic patients and those with the acute surgical emergencies, such as strangulated hernia, are considered most fitting. People with pulmonary or renal or cardiac disease run less risk by this method, and it gives good results with alcoholics and diabetics. Syphilis is a contra-indication. Young people take it rather badly, and Michelsson avoids it in extra-painful operations, in septic cases and in those with nervous disease.

The 400 cases in his series formed 10% of all the operations done in that clinic during that period; 261 were abdominal operations, 71 were upon the urogenital system or the rectum, 68 upon the legs. In 83.25% the anesthesia was complete for the region of operation; in 14.25% it was incomplete, but still satisfactory; in 2.5%, or 10 cases, it was insufficient, and general or local anesthesia had to be resorted to. Of these 10 failures, 5 were due to technical errors; the other 5 were unexplained. Of 9 deaths, 4 were attributed in part at least to the action of the stovain. Other complications were, collapse in 4.5%, vomiting in 6%, head and back pains in 13%, transient paralyses in 1.5%, cramps in .75%, and psychical disturbances in 1.25%. Curiously enough, 11.6% had lung complications, while in 250 laparotomies with ether, only 7.6% were so affected. Michelsson believes that although spinal anesthesia is a valuable aid to surgery, it will never, because of its after-effects, supplant ether narcosis. He concludes with the histories of those cases which were not absolutely successful.

28. Solieri advocates the operation of omental enterokleisis — surrounding the intestine with omentum — in those cases of typhoid and paratyphoid ulcerations of the ileum in which perforation is imminent. He reports one case so treated, and his recovery. [G. G. S.]

Obituary.

ROBERT AMORY, M.D.

THE death of Dr. Robert Amory recalls the debt which the physicians of to-day owe to those of the passing generation, to those skilful, bright, resourceful practitioners who at the close of the pre-antiseptic era laid the foundation of scientific medical progress, for he belonged to that class.

Dr. Amory came of a New England family, was taught at the school of Mr. Epes S. Dixwell in Boston, graduated from Harvard College in 1863 and from the Harvard Medical School in 1866. He spent a year in post-graduate work abroad. In Paris he studied toxicology and experimental therapeutics under Bergeron and Magnan; and in Dublin, midwifery at the Lying-In Hospital. Then he settled in Brookline, where he practised diligently for fifteen years. He was physician to the Boston Dispensary, a councillor of The Massachusetts Medical Society, lecturer at the Harvard Medical School on the physiological action of drugs, and from 1872 to 1875 professor of physiology in the Medical Department of Bowdoin College at Brunswick, Me. In 1869 he equipped and for several years maintained a private laboratory at 16 Lagrange Street, Boston; it was almost the only place where students and physicians could come for advanced courses in physiology, chemistry and anatomy and for research work.

As a writer he was prolific. His articles in the London *Practitioner*, the New York *Medical Journal* and the BOSTON MEDICAL AND SURGICAL JOURNAL dealt with the physiological and toxic actions of various drugs on man and on animals. He published two larger monographs, one on the action of bromide of potassium and bromide of ammonium, and one on the action of nitrous oxide on man and animals. He edited the chapters on Poisons in Wharton and Stille's "Medical Jurisprudence," which in two subsequent editions grew to a separate volume of large size. He translated into English and published Professor Kuss' "Lectures on Physiology." In 1866 he wrote a treatise on Electrolysis in Medicine, advocating its use for the removal of hairs, for the reduction and cure of certain forms of goiter and in a limited way for the treatment of uterine fibroids.

For three years he was president of the Norfolk County Medical Society and a founder of the Boston Society of Medical Sciences and of the Massachusetts Medico-Legal Society, of which he was the second president. He was also president of the National Decennial Convention in 1880 for the revision of the Pharmacopœa of the United States, and one of its Committee of Revision and Publication. Although largely interested in the therapeutic action of drugs, he was one of the first to advocate and practise the surgical drainage of empyema, and began early to perform tracheotomy for the relief of obstructed respiration in diphtheria.

Dr. Amory served in the Massachusetts Volun-

teer Militia as assistant surgeon of First Battalion of Light Artillery in 1875, surgeon of the First Battalion of Cavalry in 1876, medical director of the Second Brigade in 1877, and again as medical director on Brig.-Gen. Eben Sutton's staff from 1878 to 1881.

After 1880 he practised during the summer months at Bar Harbor, Me. In 1887 he retired from medicine to undertake a business career as general manager of the American Electrical Manufacturing Company, and later as president and general manager of the Brookline Gas Light Company.

Correspondence.

BRUGES, ANTWERP, THE BELGIANS, THE RHINE, HEIDELBERG.

[From Our Foreign Correspondent.]

HEIDELBERG, Aug. 15, 1910.

Mr. Editor: A week of rather strenuous travel and sight-seeing in Belgium and the Netherlands included little of special medical interest. At Bruges, far more memorable for the exquisite, eerie, unearthly beauty and sweetness of the chimes in its gray old belfry, we found, in the gallery of the *Hôtel de Ville*, a curious anatomical painting representing a dissector demonstrating to his class the "shirt-frill" of the mesentery. At the Hague was Rembrandt's much more famous and familiar "School of Anatomy," chiefly of interest not for its anatomic accuracy so much as for the faces of the students, which express as vividly as one still sees them to-day in the dissecting-room or at demonstration the attitudes of different minds towards the subject under study. At the gallery in Antwerp there were more "lessons in anatomy," by Rembrandt and others, of varying merit, all illustrating one aspect of that singular fondness for the gruesome which crops out here and there as a contradictory streak in the artistic temper of the medieval character. One of these in particular, representing a cadaver with the abdomen opened and emptied of viscera, the dome of the diaphragm arching above it, and the calvarium just removed exposing the brain *in situ*, was so realistic as to elicit audible shudders from many who passed before it.

The Belgians are an interesting people, not nearly as Gallic as one expects to find them, but with a considerable phlegmatic mitigation of temperament which probably represents, racially as well as etymologically, their Flemish descent. Brussels is little more than a miniature Paris, but in the other Belgian cities the national character of the people is well-marked, though it is hard to see why the inhabitants of Flanders should have preserved their racial traits so much better than their neighbors of Picardy. Perhaps the chief reason is that Flemish is still taught in the schools and maintained as a spoken language side by side with French; for its speech is the life of a nation. All the signs in the streets and many in the shops are printed in both languages, and we soon became fairly expert in reading Flemish with the help of the French "trot." From Flemish, as we thus learned it, was an easy transition to Dutch, that own cousin of Anglo-Saxon and half-brother of German. By the time we left Amsterdam we could even make the tram-conductors understand, in their native tongue, where we wanted to go, though the surprisingly prevalent knowledge of English among the people really made such efforts unnecessary. It may be an evidence of culture for an English-speaking person to be able to talk other languages, but after all it is probably better racial policy to make the other people learn English.

At Antwerp, by the way, we had the unexpected pleasure of meeting, quite casually on the street, a Boston physician, well-known to us, who had just arrived from Rotterdam. It is singular how natural such a meeting seems in a foreign city. You turn a corner and there is some one you saw last on Commonwealth Avenue or Boylston Street, and yet his being there gives you as little surprise as any of the benefactions of Providence that we accept as matter of course. It was good to shake the hand of a friend though, and hear the level, measured speech of a Bostonian again. He gave us some news from home and some counsel about our journey, then said good-bye and passed into the crowd. And when we meet him again in Boston it will seem just as natural and we shall be just as glad as in Antwerp. There is nothing like travel to teach not only the essential brotherhood of all nations, but the strength of the bonds that tie us to our own family and community.

After the Low Countries it is refreshing to get a glimpse once more of woods and mountains as one proceeds up the Rhine valley to the Fatherland. Germany is a country whose past is so full of song and legend, and whose present civilization is so rich in artistic monuments and modern activities, that wherever one goes there is excess of material for study and suggestion for reflection. At Köln we could only marvel in silence at the colossal Dom. Such stupendous works are really too great to be grasped by the ordinary mind. In the old church of St. Ursula we examined with much interest the dadoes and reliefs constructed with bones reputed to be from the skeletons of 11,000 pious virgins martyred by Diocletian near the site of the present building. It was particularly instructive to observe the admirable adaptation of the various bones, especially vertebræ, ribs and ossa innominata, to different types of pattern. Many of the effects produced were strikingly handsome and artistic, notably a herring design of fibulæ and radii, and a large rose of which every petal was a skull. The decorative possibilities of the human skeleton have never been fully worked out, and obviously should be no longer neglected.

From Köln up the Rhine is a journey full of romantic and picturesque interest, and it seems almost too good to be true when you find that all the scenes of the Rheinsaga are really there and that their beauty is even more magical than their names.

> "The castl'd crag of Drachenfels
> Frowns o'er the wide and winding Rhine"

as gloomily as when Siegfried slew the dragon there, or even in the later days of Lord Byron. Rolandseck still recalls the story of Roland and Roncesvalles; and Stolzenfels bristles upon its proud rock, though not half so imposingly as Sooneck, Falkenburg or Rheinstein a little further up the river. A magnificient thunderstorm swept past us as we went up the gorge of the Rhine, and spread its murky pall behind the Lorelei. There is small wonder at the legend which time has attached to this imposing cliff if one looks at the eddy that whirls treacherously by its base. Beyond "Fair Bingen," the valley opens out into the sunny Rheingau, surveyed from end to end by the superb national monument of Germania, set "high 'mid rock and wood," whose colossal figure seems to send a benediction of peace over fertile fields and vineyards towards the south.

After the Rhine, one might fear that all other rivers would fail to charm, but the valley of the Neckar has beauties that almost justify Scheffel's love for it as the most beautiful spot in the world. Heidelberg is of course a name to conjure with, poetically as well as academically, and the combination of attractions which it presents is fairly unequalled. There are towns that have a finer situation; castles that are more exquisitely romantic, notably Conway and Raglan and Tintagel; rivers that are lovelier; mountains and woods that are more grand and noble; but hardly a spot in any land where so many elements of beauty and association are so harmoniously united. The castle, a rich old ruin of red sandstone, is probably the center that holds all in cohesion, for it attracts your gaze first and last wherever you may be, whether from the valley below, or from the wooded height of the Molkenkur, or from the shady Philosophenweg across the river. Yet from the castle itself, the scene is most fascinating of all, proving doubtless the artistic judgment of its builders, and justifying the somewhat precocious but discriminating exclamation of a preternaturally solemn little German boy who climbed the *gesprengte Turm* with us and on surveying the view from the top said to his father in an awe-struck voice, "*Oh Papa, ist das nicht aber geistreich?*"

Three days are all too few to give to the appreciation of such beauties as those of Heidelberg, and at the close

of them it seems that we have but just begun to see something of their meaning. Of the University we saw nothing but the exterior, for it is now vacation. The hospitals are interesting and deserving of much more attention than we could give them. We visited the Frauenklinik in particular and were cordially received and shown about by the *Assistent*. Obstetrics thrives in Germany but differs little in the details of its practise from that in other countries. Hebosteotomy and extraperitoneal Cæsarian are the favorite operations here and have largely supplanted the use of forceps in dealing with even moderately contracted pelves, at least in this clinic. It was rather surprising to find that the professor does practically all his private practise at the hospital, where his patients come to consult him and are received in first and second class waiting-rooms, just like passengers at a railroad station, with corresponding fees. Is this an index of what will result from hospitalization of the people in our own country?

Despite the normal recrudescence of medical enthusiasm on finding ourselves again in a hospital, we have found Heidelberg chiefly memorable, however, for the glory of its natural beauty. Our brief stay here is ended all too soon, and the recollection of this sun-steeped, breeze-swept valley, crowned by its woods and by the noble castle, will remain one of the happiest of our journey. Oxford has been called "a place to make Americans unhappy," and the pang with which one contrasts it with our own universities is almost akin to sorrow. But to study at Heidelberg should make an American student dangerously happy, for, like the Lotophagi, he would never wish again to return home.

MEDICUS PEREGRINUS.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING SEPT. 3, 1910.

FITTS, H. B., medical inspector. Placed on the retired list from Aug. 23, 1910. Aug. 26.

GROVE, W. B., surgeon. Detached from the Naval Training Station, Newport, R. I., and ordered to duty at the Naval Medical School Hospital, Washington, D. C. Aug. 27.

LEVS, J. F., surgeon. Detached from temporary duty in the Bureau of Medicine and Surgery, Navy Department, and ordered to the Naval Training Station, Newport, R. I. Aug. 27.

CATHER, D. C., passed assistant surgeon. Detached from the Naval Academy and ordered to the "Iowa." Aug. 27.

PRYOR, J. C., surgeon. Detached from the Navy Yard, Pensacola, Fla., and ordered to the Bureau of Medicine and Surgery, Navy Department. Aug. 30.

JENKINS, H. E., assistant surgeon. Detached from the "Franklin" and ordered to the "Montana." Aug. 31.

HERMESCH, H. R., assistant surgeon. Detached from the "Montana" and ordered to temporary recruiting duty at Knoxville, Tenn. Aug. 31.

THOMAS, G. E., assistant surgeon. Detached from the "Dubuque" and ordered to temporary duty at the Naval Hospital, Marc Island, Cal. Sept. 1.

INTERNE, GOVERNMENT HOSPITAL FOR THE INSANE.

AN examination will be held Oct. 5, 1910, to fill a vacancy in the position of medical interne in the Government Hospital for the Insane at Washington, D. C.

EXAMINATION FOR PHYSICIANS, UNITED STATES CIVIL SERVICE COMMISSION.

THE United States Civil Service Commission announces that an examination will be held Sept. 14, in various cities throughout the country, for physicians to fill vacancies occurring in the various services. Applicants must be between their twentieth and fortieth year, and positions are open only to men. Full information may be obtained from the Manual of Examinations revised to July 1, 1910, Sect. 197. Applicants should at once apply for a copy of the Manual of Examinations and the proper application forms either to the United States Civil Service Commission, Washington, D. C., or to the secretary of the board of examiners as follows: Post Office, Boston, Mass.; Philadelphia, Pa.; Atlanta, Ga.; Cincinnati, O.; Chicago, Ill.; St. Paul, Minn.; Denver, Colo.; San Francisco, Cal.; Custom-House, New York, N. Y.; New Orleans, La.; Old Custom House, St. Louis, Mo. No application will be accepted unless properly executed and filed with the Commission at Washington.

SOCIETY NOTICE.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION. — The twentieth annual meeting of the American Electro-Therapeutic Association will be held at Saratoga Springs, N. Y., Sept. 13, 14 and 15. There will be an exhibition of electrical apparatus in connection with the meeting.

RECENT DEATHS.

DR. H. V. DAY, of Butler, N. J., died of cancer on Aug. 29, after an illness of eighteen months. He was a native of Morristown, N. J., and fifty-seven years old.

EDMONDS, LOUIS, M.D., M.M.S.S., of Roxbury, Mass., died Sept. 1, at the Boston City Hospital, after a brief illness, aged sixty-two years. Dr. Edmonds after a period of activity as a newspaper compositor began the study of medicine late in life and was graduated at the Harvard Medical School in 1893. He served thereafter in the Worcester City Hospital and became a member of The Massachusetts Medical Society and of the American Medical Association. After leaving the Worcester Hospital he practised for eleven years at Harwich, Mass., and later was physician at the leper colony on Penikese Island. He had great interest in leprosy and took part in the early discussions regarding the establishment of a leper colony in Buzzards Bay.

Original Articles.

THE PRESENT STATUS OF THE TREATMENT OF EXOPHTHALMIC GOITER.*

BY JAMES MARSH JACKSON, M.D.,
AND
THEODORE JEWETT EASTMAN, M.D., BOSTON.

In considering the subject of exophthalmic goiter we are immediately impressed by the tremendous rapidity with which our knowledge of certain aspects of it has advanced, for, unknown and unrecognized comparatively few years ago, its bibliography now numbers many hundreds of articles in all languages. While it must have existed long — perhaps for centuries — before it was first described in medical literature, it was only after the attention of physicians was called to it by Parry that it began to be noticed. Dock,[1] in his comprehensive article on the history of the disease, tells us in a few pages all that we know of its history. The earliest description that he found was by Flajani, probably before 1820. Parry, of Bath, England, gave in 1825 a fairly accurate and keen description of a case seen by him in 1786 of very marked exophthalmic goiter following confinement, and later he saw seven others. No other good descriptions of the disease were given until 1835, when Robert James Graves, a renowned physician of Dublin, described with great fullness three typical cases.

Following this, in 1848, came a very thorough article on four cases observed by Carl A. von Basedow, of Merseburg, a small town in Germany. With this article was a full bibliography, and an inquiry into the pathology of the disease. Graves did not attempt to give a name to the disease, but Basedow called it "goggle-eyed cachexia." The name "Basedow's disease" seems first to have been used by Hirsch in 1858, and "exophthalmic goiter" and "Graves' disease" were first applied to it in 1860 by the great Trousseau, who was a firm admirer of the Dublin physician.

A discussion on the disease in the Paris Academy of Medicine in 1860 created great interest in it, and many articles soon appeared, including those of Von Graefe and Marie and Moebius, and this interest has so grown that when Kocher made his great bibliography on the subject in 1902 he was able to find 1,423 titles.

There have been few diseases as to the origin of which more theories have been advanced than concerning exophthalmic goiter. Heineck[2] mentions seven theories which have been held, among them the cardiac, which assumes that the tachycardia is primary and the other symptoms are all secondary to it; the sympathetic, which assumes that all the symptoms are due to a disturbance of the sympathetic nervous system; the nervous, which has its basis in the fact that a neuropathic family history is found in some cases; the parathyroid and the thymus theories, which attribute the cause of the disease to disturbances in these glands, and, finally, the thyroid theory, the one which carries greatest weight at present and which is substantiated by clinical, experimental and pathological evidence.

Of the first four theories, that regarding the sympathetic nervous system is the only one which seems to have any evidence in its favor. Jonnesco[3] claims a considerable number of cures of the disease through severing the cervical sympathetic nerves leading to the thyroid gland, but there is practically no other advocate of this practice now. Changes have been found in the parathyroid glands in a number of cases, but injury of these glands has failed experimentally to produce the symptoms of Graves' disease. Falta, who with Eppinger and Rudinger has done the best work on the relation of the glands of internal secretion, explains the occasional occurence of lesions of the parathyroids by saying[4] that "on account of the close approximation of the parathyroids to the thyroid gland, functional disturbances of the parathyroid may occur as a consequence of rapid strumous enlargement or inflammation of the thyroid." As for the thymus theory, autopsy statistics have not shown any connection between persistent thymus and Graves' disease. The theory that the thyroid gland is alone responsible for the disease is the only one that has survived, and this is borne out by experimental and clinical evidence. It is found that the administration of thyroid extract will produce the symptoms of the disease,[5] and pathological examination of the thyroid gland in cases of it constantly shows changes, proving that there is a hypersecretion of the thyroid juice either from an increase of normal thyroid tissue, or simple hypersecretion by a normal sized thyroid.

The manner in which the symptoms of the disease are produced by this hypersecretion has been much discussed, but from all the evidence it seems most probable that the secretion acts on the sympathetic system, perhaps directly on the *chromaffin substance* which it contains, which is in itself a gland and, therefore, most likely to be acted upon by another gland, as is so frequently the case. It is not impossible that we are dealing with a vicious circle. It is acknowledged that the glands are controlled by the sympathetic nervous system: something — in many cases apparently a mental shock — excites this system which brings about an increased thyroid secretion; this in turn reacts on the sympathetic system for which it seems to have a special affinity. The thyroid is in this way still further stimulated and we have a vicious circle, the continued sympathetic stimulation showing its effect in the sweating, diarrhea, nervousness, rapid respiration, tachycardia, etc. Another link in the chain of evidence in favor of the sympathetic theory is shown by Falta,[6] who points out the fact that the cells of the chromaffin system and those of the medulla of the adrenal are similar; that the majority of the symptoms in exophthalmic goiter point to a hyperirritability of the sympathetic system, and so, too, adrenalin exerts its chief influence upon the endings of the sympathetic nerves.

It is perfectly possible for a gland to show great *hyperactivity* without actual enlargement just as

* Read at the annual meeting of The Massachusetts Medical Society, June 7, 1910.

do the salivary glands in a case of salivation. Furthermore, it is possible that some change in the *quality* of the secretion may produce the symptoms without any increase in the quantity.

The gland may be scarcely perceptible to the touch in a patient with very severe symptoms, and, on the other hand, the victim of a very mild attack of the disease may have a large goiter.[7] In this latter case the goiter is made up mostly of colloid,[8] but cystic or colloid degeneration may come on in plain goiter and may cause hyperthyroidism, probably by pressure on the thyroid tissue, just as in a polycystic kidney the pressure causes a nephritis. Again, a colloid goiter may suddenly become active and produce the worst type of Graves' disease, because nature suddenly tries to bring the degenerating gland to life again and creates a lot of new epithelium.[9]

Now a few words as to diagnosis. Palpitation and tachycardia are the commonest early symptoms; then, possibly, an increase in the size of the thyroid. Exophthalmos may be present relatively early and then may follow some or all of the symptoms which we find in the most marked cases. Nervousness, an anxious expression of the face, pallor, tremor, diarrhea, sweating, frequently a slight albuminuria and occasionally glycosuria through a sympathetic disturbance of the pancreas by the thyroid, as has been shown by Falta.[10] The signs (v. Graefe's, etc.) found in the eyes may or may not be present. In practically every case, however, we find some abnormality of the heart. In the earliest stages it is only rapidity of the beat, but before this has gone on very long we are sure to find some evidence of a myocardial affection, — weakness, irregularity in rate, rhythm or strength, and hypertrophy and dilatation. In fact, myocarditis of some degree is one of the most constant lesions of the disease.

In rare cases an abnormality of position of the thyroid may exist. We saw a short time ago a patient with extremely marked symptoms of Graves' disease, but were unable to find by palpation any traces of a thyroid. On percussion, however, there was dullness below both clavicles, and at operation (which was successfully accomplished) it was found that the case was one with a so-called "dipping thyroid," and that the lateral lobes were located in the position shown by percussion. Another case which came to our attention showed a very much enlarged left lobe in its normal situation, whereas the right lobe occupied the position of the apex of the right lung and was nearly the size of a cocoanut. In cases like these we are often mystified by the very marked dyspnea without any sign of an enlarged thyroid. This dyspnea may come on only in attacks following "catching cold" or getting overtired or at the time of menstruation on account of the swelling of the thyroid at those times producing pressure symptoms and is a great element of danger in that the pressure may give rise to emphysema and bronchitis and result in overloading of the heart with consequent cardiac failure, or the thyroid may swell suddenly and to a large size and suffocate the patient.

Kocher [11] has shown that there is a characteristic blood picture in the disease. In his analysis of 106 cases he shows that the red cells are somewhat increased and there is, as a rule, no anemia. The white cells are most affected. There is a marked diminution in their numbers, going as low in one case as 3,700 to the cubic millimeter. As a rule, the neutrophiles only are affected, being reduced often to as low as 35% instead of the normal 50% to 57%. The lymphocytes, on the other hand, showed sometimes an absolute but more often a relative increase, even to 57% instead of the normal 25%. Werelius [12] says that this picture is characteristic of exophthalmic goiter and is most marked at the height of the disease, and it has been shown in many cases that the blood returns to its normal conditions following a successful operation. This blood picture agrees with the long-recognized fact that starvation, cachexias and nutritive disturbances increase the lymphocytes in the circulating blood. Furthermore, in exophthalmic goiter we have, besides the profound change in nutrition, a marked chemotoxic action on the lymph system by the excessive thyroid secretion thrown into the circulation. The more severe the hyperthyroidism and its constitutional changes, the greater the lymphocytosis, and Kocher [13] contends that this condition is a contraindication to immediate operation if such can possibly be avoided. The utmost endeavor, he says, should be made to treat these cases medically and restore their nutritive balance until the fall in lymphocytes shows that the patient's resistance has been so built up as to make the operative risk at least a reasonable one.

As has been already suggested, we may find hyperfunction and degeneration in the same thyroid gland. Thus we may have together the causes of exophthalmic goiter and of myxedema, and it is a fact that we find cases presenting clinically symptoms of both diseases. These are patients in whom the major part of the gland has been destroyed by degeneration and who would be myxedematous were it not for the fact that the preceding hyperthyroidism has produced a myocarditis which accounts for the tachycardia, while the exophthalmos and nervous symptoms persist. It may thus be seen that many cases — in fact, it is stated as many as 50% — are destined to recover from Graves' disease if they can be tided over the acute stage.

How may we best accomplish this? Two methods of treatment are open to us: surgical, by which we remove the cause of the disease, and medical, by which we endeavor to palliate the symptoms and keep the patient going, — and in this connection we want to emphasize the great importance of the medical man and the surgeon studying the cases together, for there is no disease in which each can work more to the advantage of the other than in this one.

Let us consider first the medical treatment, and this means to a great extent the treatment of the tachycardia, for when we allay that we also diminish the other nervous symptoms; and, further, the heart is the organ most needing protection.

In fact, the medical treatment of exophthalmic goiter may be expressed as the treatment of myocarditis: in the early cases we treat it by prophylaxis, try to prevent its occurrence; in the later cases we try to remove its cause, and in very late cases we try to palliate the existing condition and save what heart muscle is left.

The etiology of this myocarditis has been disputed. It is by some regarded as a result of overwork through pressure on the vagus, by others as a result of direct toxic action on the myocardium by the thyroid secretions, and by Romberg and others as a result of nervous stimulation.

In some cases the direct cause of an overworked and later dilated heart may be the emphysema and bronchitis brought about by compression of the trachea or bronchi by a large thyroid, but in the greater number of cases it seems to me that the cardiac condition is brought about by a primary stimulation to greater rapidity by the thyroid secretion, with a resulting malnutrition of the heart muscle on account of the shortened diastole.

In the treatment of this condition we resort to these measures: *to rest the heart and to diminish the thyroid activity*. Here the most important factor is rest, — absolute rest, — not only physical but mental rest as well. Since the patient is usually in a very highly nervous condition we must first insist upon her remaining in bed, in the quietest room in the house, or in some place away from home, especially in cases where there is any exciting or worrying factor in the household, or, indeed, anything to modify the most perfect conditions for mental quiet; in short, the so-called "Weir Mitchell rest cure" should be rigidly enforced in its strictest form. To care for the patient, we must find a nurse whose effect on her will be soothing. The diet must be nourishing and easily digested, tea and coffee forbidden or greatly limited, and alcohol and tobacco absolutely forbidden. The tachycardia and to some extent the nervous symptoms can often be markedly diminished by an ice bag over the precordia, and occasionally constant cold applications over the thyroid are also of value by retarding the action of the gland and thus diminishing the output of secretion. Cold sponges, cold wet packs and in some cases prolonged cool baths are found to exert a marked soothing effect. At times the bromides in doses of 10–30 gr. three times daily may be successful in diminishing the tachycardia and nervous symptoms, but opium should be avoided whenever possible.

The drugs usually used in cardiac cases we find of little avail. Digitalis, our common reliance in slowing the heart beat, has little effect since it does not reach the cause of the tachycardia, and in exophthalmic goiter it easily causes gastric upsets. Strophanthus and spartein sulphate are also of little use, but in some of the more advanced cases with cardiac weakness small doses of strychnia are sometimes valuable. We have found in a large series of cases that the drug which gives the best results has been the neutral hydrobromide of quinine, the use of which was first suggested by Dr. Forchheimer, of Cincinnati. It is important that a strictly neutral salt be used, as the acid salt which is frequently dispensed does not give as good results, and we have had the best success with that made by Parke, Davis & Co. It is given in capsules containing 5 gr. each, and to the limit of the patient's tolerance, which is rarely more than three or four capsules a day. Toxicity is shown by the appearance of tinnitus, and no further ill effects are experienced if the medicine is temporarily stopped when this appears. The administration of this medicine must be continued for a long time and it is well to tell the patients in the beginning that they will probably have to take it for months or even for two years or so. If this is not done, the patients are apt to become discouraged if they see no marked results after a few weeks. Very frequently the patients notice after a week or two of the treatment a diminution of the palpitation, the sweating, the tremor and other nervous symptoms, and in many cases the thyroid diminishes in size. The exophthalmos seems to be the last of the signs to disappear, and this may not be until the expiration of two or three years, while rarely the exophthalmos and tremor may persist more or less even after all subjective symptoms have disappeared. When this last occurs, the dose of the drug should be cut down even to two or three capsules a week, the patient being cautioned, however, to resume immediately the former dose at the first appearance of any of the old symptoms.

Our cases have often proved to us the close connection between the thyroid gland and the genital organs. For instance, we have noticed that if the patient becomes pregnant the symptoms are often held in abeyance during the pregnancy, returning, however, after confinement. Again, relapses may occur at the menopause, and, in fact, one of us has just seen a case that has been entirely well for seven years but has recently had a relapse coincident with the climacteric. When relapses occur, as is not uncommon, an active resumption of the treatment quiets them quickly. We are not certain how the quinine acts, though it seems most probable that it acts on the sympathetic system and thus puts an end to its stimulation of the thyroid and the vicious circle which has already been mentioned. We can easily assure ourselves of its specific action by discontinuing its administration in any case and noting the prompt return of symptoms.

In tabulating the results of this treatment on our patients at the Massachusetts General Hospital two years ago with Dr. Mead, it was found that of 56 cases under observation for from three to nine years whom we were able to examine and talk with, 76% had had no signs or symptoms for two years, while 13% had been benefited and only 6 cases (11%) could be considered failures. These cases which we regard as cured are able to perform their ordinary daily work. It is, of course, the early cases that do best under this treatment, and in the very advanced cases with organic changes in the heart we can hardly expect a cure, but we do often see a radical change for the better.[14]

With thyroidectin, the dried and powdered

blood of thyroidectomized goats, we have not obtained satisfactory results. Moebius [15] reports several cases in which the symptoms have been diminished by this treatment, but he has not published any cures through its use. Some of our early cases were treated by subcutaneous injections of the serum of thyroidectomized goats, and in a few cases we got good results, especially on the exophthalmos and on the goiter. The serum is, however, very expensive, and some patients object to the frequent injections; and, further, it is not a treatment that can be carried out by the patient at home. The milk of thyroidectomized goats in its original or the powdered form, and "Rhodagen," a preparation made by drying the proteids precipitated from the milk by alcohol, have been used to some extent abroad, but they are hard to get, are expensive, for the goats soon become myxedematous, and, furthermore, no marked benefit has ever been reported from their use.

A few years ago Rogers and Beebe,[16] of New York, brought to our notice a serum treatment. Believing that the symptoms of the disease are caused by hyperactivity of the thyroid, they prepare a serum which is to neutralize, as does an antitoxin, the toxic action of the proteid in the thyroid secretion, and also by its specific toxic action on the secreting cells of the gland to diminish or stop the manufacture of these injurious proteids.

To prepare this serum the proteids are extracted from fresh human thyroid and injected into animals. After several doses have been given, the blood of these animals, which has now become loaded with antibodies, is withdrawn and the serum injected into the patient.

In certain types of cases [17] — those in the transitional stage, where the formerly hyperactive thyroid is undergoing colloid degeneration and where we find a curious mixture of the symptoms of Graves' disease and myxedema — Rogers and Beebe use what they term the "combined treatment." In this they use the serum we have just described to combat the conditions of hyperthyroidism, and at the same time give an extract of sheep's thyroid to neutralize the hypothyroidal or myxedematous conditions caused by the degeneration of part of the gland. One would naturally think that the serum would neutralize the extract of the sheep's thyroid, but this, the authors claim, is not the case. Rogers' latest published results [18] are not as good as his earlier ones, for in 480 cases of all grades he claims only 15% of cures, removal of the subjective symptoms in 10%, and 50% improved to such a degree that they disappeared after one or two months' treatment because of the relief of symptoms. These cases, then, are lost, and we do not know whether they are better or worse. Seventeen per cent were unimproved and 8% died from the natural course of the disease.

They lay great stress on the importance of properly selecting the cases suitable for the different treatments and on the amount and frequency of dosage, and say that it is impossible to make hard and fast rules, but each patient must be carefully studied and treated accordingly. Exophthalmos and goiter are the last signs to disappear, and while the latter persists the patient must avoid mental or physical over-exertion for fear of a return of the symptoms.

The principal objection raised to this form of treatment has been the possibility of injury to the rest of the organism by a cytotoxic serum strong enough to act upon any one of the tissues, as this serum is supposed to act upon the thyroid epithelium.

Electricity in several forms has been used by a good many, but there is very little evidence that any form of it is of value except the x-ray. Cook,[19] Beck,[20] Freund,[21] Price,[22] Holland,[23] Garré,[24] and others report excellent results from its use, and all report a very great drop in pulse-rate after two or three treatments, in several cases the pulse dropping to normal after a few exposures and with this a great improvement in the subjective symptoms. It is thought that the x-ray causes the secreting tissue to shrink, and perhaps to some extent kills it, and in this way the secretion of the toxins is checked. As an adjunct in certain cases this treatment is certainly of value.

Let us now consider the other alternative, surgery, and first let us emphasize the importance of the surgeon's being an expert at thyroid operative technic, for the liability of injury to the parathyroid or to the recurrent laryngeal nerve and of hemorrhages in the hands of the inexpert are too great to be overlooked. What are the indications for operation? The opinion of some surgeons is still that *diagnosis is the indication for operation*,[25] but that opinion is one which should be considerably modified in view of the success of medical treatment in a good percentage of cases. Certain types of cases require prompt operative treatment. Such cases are those in which the goiter is a mechanical danger, as, for instance, when it compresses the trachea or esophagus, or both. Here you get interference with swallowing or with breathing, and frequently cough and occasionally a dangerous bronchitis. The diagnosis is easy in the ordinary case when the enlarged thyroid can be palpated, but in cases with "dipping thyroid" the diagnosis is sometimes very blind. The greatest danger lies, not in the continued bearable pressure, but in the liability to sudden enlargement of the goiter, which not infrequently occurs, and which may quickly suffocate the patient. This point has been very strongly impressed upon us, for we have seen three cases die in this way while awaiting operation. Furthermore, this danger is so great that immediate operation is indicated in any case in which a dipping thyroid is found, even though the symptoms of exophthalmic goiter be very slight, as may happen.

Operation is also indicated when exophthalmos, by preventing closure of the lids, endangers the eyesight through corneal ulceration, or when after three months of good medical treatment there is no marked improvement in tachycardia or in the patient's general health, or there is an increase in the intoxication by thyroid secretion, even though

no enlargement of the thyroid can be demonstrated.[26] Cases with beginning cardiac involvement, — i. e., myocardial weakness, — as shown by a pulse of 130–160, or one that suddenly fluctuates in tension and rate, should be operated upon at once in order to save the heart,[27] while in cases that have gone beyond this point, and have arrived at the stage where the myocardium is badly diseased and the aggravating symptoms of exophthalmic goiter are still present, operation must be considered a last resort, not expecting a cure, but merely as an effort to prolong life by taking strain off the heart. If there is anemia with swelling of the feet, Mayo [28] puts the patient on rest and belladonna for some days, and in the severer types uses in addition the x-ray for two to six weeks. Riedel [29] emphasizes the importance of avoiding operation if possible, if there is any bronchitis from compression, since it increases to so great a degree the liability to bronchopneumonia, but in these cases it is usually better to risk the consequences of an operation than to risk a sudden swelling of the thyroid and a resulting death by suffocation.

Then there is another side of the question that must be considered,— the circumstances surrounding the patient. For instance, if our patient is a business man, dependent on himself and unable to give up the long time necessary for medical treatment and he is unable to go on in his present condition, immediate operation offers the best solution of the problem.

We shall not go deeply into the methods and technic of surgical treatment. Of the precedures [30] which remove the thyroid tissue, excision, as done by Kocher, and resection, as done by Mikulicz, are most frequently done, while Porta and Socin's method of enucleation without disturbing the posterior portion of the capsule offers the least liability of injury to the parathyroids with the resulting tetany. This however, is a very uncommon accident at the hands of experts. Horsley's procedure of division of the isthmus on the assumption that it would be followed by atrophy of the lobes has not been successful, and excision of the cervical sympathetic ganglia, as proposed by Edwards and later used by Jaboulay (1896) and Jonnesco, has been proved experimentally by Schiff to have no effect on the thyroid. Curtis,[31] however, reported in 1903 that Jonnesco had done 17 bilateral operations of this sort with 60% of perfect cures and no deaths. Ligation of the thyroid arteries — Wolfler's operation — is of value. In some cases this alone has produced cures, but it is most valuable as a preliminary to the radical operation in severe cases.[32] There is the danger of including the recurrent laryngeal nerve in tying the inferior thyroid artery, with resulting laryngeal paralysis and inhalation pneumonia, so great care should be taken that this does not occur. Ligation of the superior artery and vein, as is now done especially by the Mayos, is safe, but in many cases is not sufficient. In their latest paper [33] they report 2% of deaths within a few days after operation. For some unexplained reason acute thyroid poisoning may follow either of these last two methods of operation as well as those in which the thyroid tissue is cut and otherwise subjected to trauma.

Crile [34] lays special emphasis upon the importance of mental quietude preceding the operation. He so handles the patient by rest and sedatives that she is not worried and excited by the approach of the operation, nor is she conscious of taking the anesthetic, and, indeed, he claims that the patient in some cases does not realize that the operation has been done. This method he terms "stealing the gland," and certainly his results are remarkably good.

Quiet *following* the operation seems to me to be equally important, for frequently the patient is fuller of thyroid toxin at this time than at any other.

Capelle [35] has called attention to the importance of ascertaining when possible the presence of a persistent thymus, for in unexplained cases of death following operation the thymus was found in many cases to be of the size commonly found in the newborn. This gland, lying just behind the upper part of the sternum, is very difficult to make out by percussion, particularly as it lies surrounded by a mass of fat which not infrequently leads to a wrong diagnosis. The x-ray helps us very little if any here, and if we find dullness on percussion over this region we are between two risks, — that of operating in the presence of the apparently present thymus, and that of depriving the patient of the benefit of an operation when the mass is a false thymus consisting merely of fat.

It is well known that persistent thymus predisposes to death under ether, and in many cases collected by Capelle death occurred ten to twenty hours after successful operation, with gradually increasing weakness of the heart without apparent cause. In other cases there was sudden death during the operation. Capelle does not believe that hyperthyroidism has anything to do with the sudden deaths, but considers the thymus responsible. In 60 such cases following operation for Graves' disease, 79% showed a large thymus, and of the cases of Graves' disease which died of intercurrent diseases, 44% had large thymus. Of those who died of exophthalmic goiter alone, 82%, and of those who died during operation, 95% had large thymus. Its presence, then, if it can be made out surely, contra-indicates operation.

Another contra-indication to operation is an acute exacerbation of the symptoms. If this occurs we must treat with rest, baths and sedatives until the symptoms subside. Furthermore, the condition of the heart must be carefully considered and the effect of exercise or excitement studied. In other words, if there is dilatation, marked hypertrophy or myocarditis, operation should be avoided. This means that operation, if done, must be done before any advanced symptoms of cardiac involvement appear; and it is very poor judgment to advise operation in any desperate case.

Following operation, we expect a very marked diminution in the subjective symptoms in a large percentage of cases. The exophthalmos and tachycardia, however, may persist or even increase

after the operation, and a total disappearance of exophthalmos can be expected only in those cases in which operation is done early. A case is occasionally seen in which the exophthalmos has increased after operation, though the pulse may be normal. We have recently seen a case in a girl in whom the operation removed all symptoms; she feels and apparently is perfectly well, her pulse is 80, and she is living her ordinary life, but with a steadily increasing exophthalmos, which may in time endanger her eyesight.

The theoretical course of goiter is to go on to degeneration, which means myxedema in the end. If this is true, it may be said that by removing a large portion of the gland we are merely hastening the advent of myxedema, and yet in the cases in which operation has been done years ago, myxedema has not yet appeared. This may be owing to the fact that other glands, perhaps the chromaffin system (that is, the cells we find in the medullary portion of the adrenals and scattered through the sympathetic system, particularly in the ganglia), takes up some of the functions of the degenerated thyroid.

Now to sum up in a few words: In practically every case it is our duty to treat the patient medically, as I have already outlined, for three months. If at the end of that time no improvement has taken place, preferably ligate the vessels. This may effect a cure. If it does not, and the patient later comes to the operation of partial thyroidectomy, — which is as yet the most satisfactory of the radical operations, — the ligation will make the operation easier and less dangerous. If the goiter is very large, it is well to remove only the larger lobe and then treat the remaining lobe with the x-ray and medical procedures.

Cases that show beginning cardiac failure should be operated upon as soon as possible after putting the patient in fair condition by medical treatment. Many cases, however, come to the doctor only after the myocardial changes have begun. Patients in this condition must be treated as cases of advanced myocarditis, for all treatment beneficial to this condition is also beneficial to the exophthalmic goiter. The treatment which I have mentioned — the strictest rest, with ice bags over the heart and thyroid, a carefully regulated diet, the hydrobromide of quinine, and, if necessary, the cautious use of strychnia and bromides — must be carried out. We must not expect an absolute cure in the cases where the myocarditis is advanced, though symptomatic recovery does sometimes occur, and we can hope only to lessen the symptoms and make life better worth living for the patient and the patient's family. The earlier cases we may be able to cure, and if not we may, by careful medical treatment, improve their condition to such an extent that they can be operated upon with much less danger than before treatment.

Gentlemen, — The last word in the treatment of exophthalmic goiter has not yet been said and we are still a good deal in the dark regarding it, but I hope that I have made clear to you the indications for treatment which have met with the greatest success so far.

DISCUSSION.

DR. C. FROTHINGHAM, JR., of Boston: As Dr. Jackson's complete paper seems to cover the whole subject, I will simply try to emphasize a few of the points which seem to me to be of special interest. Although it is pretty generally admitted that the disease is due to a hypersecretion of the thyroid gland, the cause of this increased secretion is not clear. From a morphological point of view some pathologists say that there is an increase of glandular epithelium shown by infoldings. Other pathologists, however, deny that this condition is specific for Graves' disease. The chemists find some variation in the chemical properties of the gland in certain cases which might call forth an increased secretion, but no definite condition common to all these cases. Recently Dr. John Rogers, of New York, has worked out an elaborate theory for this hypersecretion dependent upon the interrelation between the chromaffin system, the pancreas and the thyroid. This theory up to the present time lacks confirmation by experimental evidence. In addition to the increase of secretion is the possibility of the increased secretion being abnormal. On this point there is considerable difference of opinion. Thus it is evident that there is a big field open for more work directed towards clearing up the true nature of this disease.

There is one point in regard to diagnosis which should be emphasized, and that is the question of whether the individual case is one of hyper- or hypo-secretion. For after the hypersecretion has ceased and there is even a dimunition of secretion, the symptoms of exophthalmos and tachycardia may persist. In these cases the exophthalmos has become permanent, due to structural changes, and the tachycardia is the result of myocardial degeneration. To operate in such cases in order to diminish the secretion would, of course, be useless. Careful history taking and physical examination ought to clear up the point.

Whether or not to advise surgery in the treatment of this disease is difficult to decide. This is due to the fact that the present statistics are unsatisfactory. They are unsatisfactory for two reasons: the same authors rarely compare good medical treatment with the same treatment plus operation, and authors will not confine their reports to only those cases that have been observed many years. That surgical intervention will give more prompt temporary relief seems pretty well established. The uncertainty exists in the end results. Therefore the circumstances of the patients make a considerable difference in the line of treatment to be advised. For proper medical treatment the patient should have absolute rest. This of course is impossible for patients in our big general hospitals and for the poorer classes in their homes. Therefore, unless future statistics show that the end results of surgical treatment are a failure, some form of surgical treatment should be recommended for those who cannot afford proper medical treatment earlier than for those who can.

DR. C. A. PORTER, of Boston: I have just read a paper upon the surgical treatment of exophthalmic goiter, in which I endeavored to make a plea for surgery in selected cases in which adequate medical treatment for a number of months did not prove successful. I tried to bring out clearly that in operating upon cases of Graves' disease, the object of the operation is different from surgery in cases of fibroids of the uterus or diseases of the appendix. In the latter, surgery may properly be said to cure, that is, to remove the cause, but in exophthalmic goiter all the surgeon can attempt to do is to modify the function of a gland which for

various reasons is functionating excessively or abnormally. It must, therefore, be understood that the results will be good or bad, depending upon the wise selection of cases and the operation done; whether it be ligation of the vessels or partial thyroidectomy. I feel quite sure that too many cures have been claimed both to medicine and surgery without waiting an adequate time to see what the end results will be. The general practitioner must remember that there is a mortality from 8 to 10% under medical treatment. This mortality, I believe, could be very distinctly reduced, probably halved, if surgery had been resorted to at an earlier period. We must never forget that this disease, once advanced to a certain stage with accompanying degenerations of the heart, nervous system and vessels, is absolutely incurable, though under medicine or surgery the patient's condition may be somewhat improved. Whoever has seen a case of acute hyperthyroidism successfully operated upon cannot doubt that the diminution of secretion of the gland has struck at the root of the evil. I feel that in Graves' disease we have one of the best opportunities for co-operation between the physician and surgeon, and the use of experience and judgment in the selection of a time when medical treatment should cease and surgery begin.

Dr. J. C. Munro, of Boston: I have just been congratulating them upstairs on the brotherly love that is dawning between the surgeon and the medical practitioner.

I endorse everything that Dr. Porter said.

Dr. Eben C. Norton, of Norwood: I would simply add that I have used serum in three cases of exophthalmic goiter, in one case beneficially and in two cases negatively.

THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.*

BY CHARLES A. PORTER, M.D., BOSTON.

When I agreed to read a paper upon the surgical treatment of exophthalmic goiter before this section, I had no idea that such excellent résumés of the whole subject were so soon to appear in our Medical Journal, written by Dr. Channing Frothingham, Jr., and Dr. J. G. Mumford. The subject, however, is one of growing importance and no harm will be done by bringing it up again, perhaps from a slightly different point of view.

While in this community the disease is commonly regarded as a medical affection, to be treated along the lines which Dr. Jackson will discuss fully in another section, the advances made by surgery in the past ten years have established without question the superior advantage of operation in properly selected cases. In spite of the newer treatment by sera and other therapeutic measures, a definite proportion of these cases go on to a rapidly fatal issue, or to myocardial and vascular changes which after a longer or shorter time are followed by death. Acute Graves' disease passes unrecognized even now, and a mortality of 5% to 10% in hyperacute cases 15% to 20%, should teach us that exophthalmic goiter may be far different from the disabling, chronic but perhaps ultimately curable disease which many think it.

The excellent results of Kocher, Charles Mayo, Crile, Klemm, etc., show an operative mortality which varies from 3.5% (Kocher) to 9% in a series of 888 cases gathered from various clinics by Krecke in 1909. Statistics as to the results in the way of cures are numerous and somewhat variable. Heineck claims as end results 63.7% cures in 207 cases. Mumford's analysis of 741 cases, chosen somewhat at random from different surgeons' statistics, gives an immediate mortality of 4.03%; late mortality, .66%; unimproved, .38%; improved, 22.27%; cured, 70.3%. Though these figures are interesting and any argument in favor of operative treatment as against medical treatment halts lamely when not backed up by figures, I must confess to an entire agreement with Dr. George Grile, who states his opinion as follows:

"A study of my series of 72 operations for Graves' disease, presenting as they do numerous and complex symptoms, and involving many organs, as well as the most fundamental vital processes, impresses me with the great, almost insurmountable, difficulty, I may add, the impossibility, of compiling any statistical table that accurately represents the net clinical results."

The disease itself is fatal in perhaps 10% of the cases. Most surgeons select their material for operation, and many cases of temporary hyperthyroidism must be classed in the statistics as cases of Graves' disease. What the physician wishes to know is the particular risk which an individual case runs from operation, and what are the chances of cure as compared with medical treatment. This I claim must depend upon the sound judgment and skill of the surgeon, and the stage of the disease, and cannot be estimated from statistics in per cents. In the same way in regard to cures, when once certain degenerations have developed, a cure by medical or surgical means becomes an impossibility; some cases with very acute symptoms rapidly improve with or without operation; other patients, apparently well after

* Read at the annual meeting of The Massachusetts Medical Society, June 7, 1910.

a couple of years, whether operated upon or not, have a recurrence of the disease. Many consider themselves, indeed appear, well, and might be called cured, yet careful examination after unusual mental or physical stress shows undoubted evidence that the disease was slumbering and not cured. In estimating the probable chances of a favorable outcome, the result is peculiarly dependent upon the possibility of the patient living an after-life free from care.

In spite of all the work that has been done upon the pathological histology of the thyroid gland, there is much to be learned about the abnormal physiology in Graves' disease. Gradually the older theories that exophthalmic goiter was due to intestinal toxemia or a sympathetic neurosis are giving way to the probability that the thyroid, for unknown reasons, functionates excessively, or that certain products which are there destroyed in normal individuals escape and cause a general toxemia. Kocher speaks of the disease as a thyrotoxicosis; Mayo, as hyperthyroidism. Whatever be the real explanation, the results of experimental work and operation have shown conclusively that the abnormal thyroid has to do with the symptoms in question, either primarily or secondarily, and that modification of its circulation or partial removal influence favorably the course of the disease. According to some pathologists, notably Louis Wilson, of Rochester, there is a certain parallelism between the symptomatology and pathology; others have not confirmed this view. Hyperplasia of some part of the gland is, however, rarely absent when symptoms are present, though the lightning response to psychic stimuli bears evidence that the toxemia is due to a chemical poison rapidly formed and excreted in excess.

The aim of medical treatment, absolute rest, ice bags, bromides, bromide of quinine, digitalis, etc., is to keep the patient alive until the abnormal stimulus has ceased to act; the poisons are eliminated or neutralized by antibodies, and then so to regulate the life of the individual that storms will not return. With rodagen, thyrodectine, etc., and the serum treatment of Rogers and Beebe, the object is to neutralize the toxins, and, in cases of hypothyroidism when combined with Graves' disease, to give both thyroid juice and antitoxic serum in proper proportions. The x-rays are advocated by those who believe that the gland can be atrophied and the efferent lymph channels narrowed or obliterated. Certain forms of electricity, according to reports, have proved beneficial, but it is probable that their action is in part due to suggestion combined with other hygienic measures. If a tumor is present which stimulates adjacent thyroid tissue, the surgeon by operation removes the exciting cause of the symptoms. By ligature of vessels, he brings about diminished blood supply and lessened activity. If veins and lymphatics are obliterated by ligature or post-operative scar tissue, the channels of absorption are interfered with. Finally, by partial thyroidectomy he directly attacks the source of supply.

In my opinion, too little distinction has been made between the purposes sought by operation for fibroids or appendicitis and that sought in operation for Graves' disease. In the first instances, the surgeon may really cure the disease by radical removal; in the latter, all that is actually attempted is *to modify the functions of an overactive gland*. After all the ligature operations and even partial thyroidectomy, enough thyroid tissue is left behind, which, if it hypertrophies or the patient is subjected to the same influences which brought about the original disease, may again become overactive and cause a recurrence of symptoms. If this conception of Graves' disease be a correct one, the physician or surgeon must be careful in promising permanent cures, and he need not be surprised, if examination is made with sufficient care, to find that many cures should be more properly ranked as permanent improvements. If the patient survives partial thyroidectomy, it is obvious that there will be less risk of recurrence than if the patient is treated medically, for there is less thyroid tissue by which toxins may be produced. On the other hand, as a proportion of these cases, through involution, go on to thyroid sclerosis or colloid degeneration, the danger of the development of post-operative myxedema must be considered if too much thyroid tissue is removed by surgery. In 1908 Klemm reported the results of operations upon 32 cases, most of them having been followed for several years. There were no deaths. Twenty-seven were heard from: 92% recoveries, 4% improvements, 4% failures. He advises operation as soon as the diagnosis is made. In spite of these good results, few surgeons agree with such a radical point of view, for it is now the belief that a preliminary course of medical treatment should be carried out for a varying period before operation should be considered. When symptoms of hyperthyroidism occur engrafted upon a chronic goiter, operation is usually indicated for several reasons: because of the danger of malignancy, estimated at 7% to 10% when goiters after thirty-five suddenly enlarge; secondly, because medical measures are usually unsatisfactory when the thyroid tissue is stimulated by an abnormal growth; and, finally, because the results of such operations are extremely good and relatively free from danger. To this class belong many patients operated upon in the great clinics and classified as secondary hyperthyroidism. These show temporary symptoms with periods of comparative health, and, particularly if operated upon in the interval, the mortality is very low. I have myself operated in over twenty cases without a death. The dangers are those of any serious operation requiring skill: hemorrhage, sepsis, injury to the recurrent laryngeals, possibly tetany if much of both lobes have to be removed —with injury to the parathyroids. The real question as to medical or surgical treatment arises in true cases of hyperplastic goiter without marked enlargement, but presenting all grades of hyperthyroidism or thyroid toxemia. In these cases, the operative and post-operative mortality is considerable and very difficult to determine from the statistics at hand, for no proper distinction is made between these two

classes of cases, and the relatively small mortality of the former when classed with the latter diminishes unduly the mortality of true exophthalmic goiter. I have operated upon only eight real cases of exophthalmic goiter with one death one hour after operation. Here the surgeon is confronted with the risks of hyperthyroidism developing usually soon after or within forty-eight hours of the operation for which careful technic does not appear to be a preventive. Such an experienced surgeon as Charles Mayo reports 2% of deaths following simple ligature of vessels. In most of my cases, convalescence has been rather stormy, — for a few days fever, varying between 101° and 103°, rapid, bounding pulse, dyspnea, etc., — but in none of them, with the exception of the fatal case, did the condition cause any anxiety. Of the seven cases surviving the operation, six have been markedly improved; none have been cured. In the seventh, marked exophthalmos with conjunctivitis and rapid pulse led to immediate operation to prevent corneal ulceration. Owing to the carelessness of the etherizer, the eyes at first covered by vaseline and protective tissue were exposed for an hour to ether vapor and a most severe inflammation developed. The operation, hemithyroidectomy, was satisfactory, the patient leaving the table in good condition. There were well-marked symptoms of toxemia for two days after the operation, which were followed by such a severe ocular infection that the patient had to be transferred to the Eye and Ear Infirmary. Pain was extreme, the patient became delirious, and at the end of three weeks death seemed imminent. Upon withdrawal of the atropin, however, the low, muttering delirium with rapid pulse disappeared, the eyes slowly cleared up, and the patient is now convalescent in spite of complications which were peculiarly unfortunate after an operation for Graves' disease.

Another case, a chauffeur of thirty, had suffered for a year from typical symptoms, which during the past two months, in spite of good medical treatment, were rapidly getting worse. I saw him with Dr. Proctor, of Sandwich, Sept. 8, 1909. At this time he was very nervous; tremor; bounding pulse of 140 which shook the chair in which he sat. Under absolute rest in bed and bromide of quinine for three weeks he improved somewhat; the severe attacks of palpitation ceased; the pulse varied between 98 and 110, but he did not gain in weight. On Oct. 2, 1909, the right half of the gland was removed and the superior thyroid vessels tied on the left. For several days there was fever and tachycardia, but the patient expressed himself as feeling distinctly better, less nervous and no palpitation. Thirty-five days after operation, the patient had gained 15 lb., was still improving, but the pulse varied between 94 and 104. The left lobe has undergone some compensatory hypertrophy. March 9, 1910, five months after operation, patient within 4 lb. of his regular weight; pulse averages between 80 and 90; in my office, 116. When quiet, feels perfectly well, but, under excitement or after walking fast, heart begins to beat rapidly. Patient has been under bromide of quinine since operation. Further operation was advised, and on March 19, 1910, the upper half of the left lobe was removed. More severe reaction after removal of half of this lobe than previous removal of half the gland. Discharged on the thirteenth day. Two weeks later pulse was 74 in the morning and 88 in evening; has entirely lost his nervous feelings, but has not yet recovered his strength. In this case, owing to inadequate removal of tissue at the first operation, a second one was necessary.

Case III. Man of twenty-eight; six months ago, after business stress, extreme nervousness, insomnia and loss of weight. Treated for nervous prostration and sent to the woods. Two months later goiter developed with tachycardia and loss of 50 lb. Patient had collapse on way to office. Examination showed typical and excessive thyroid toxemia; pulse was 165 to 170; marked tremor of fingers; some exophthalmos; patient could not sit still a second; profuse perspiration; cardiac enlargement; very vascular goiter with loud bruit. After three weeks of absolute rest in bed with ice bags, bromide of quinine, etc., the general restlessness improved, the pulse fell to 110, but loss of weight continued. On Aug. 24, 1909, I removed the right half of the gland under ether. After operation, the pulse rose to 150 and temperature to 102.5°, but on the sixth day the temperature was normal and the pulse had fallen to 100. Patient was infinitely less nervous and could rest calmly quiet in bed; his weight fell to 115. Yesterday, nine months after operation, he reported again. He has been at work as business manager for three months; considers himself well, but gets tired at night. He has a ravenous appetite and has gained 45 lb. There is no exophthalmos; pulse is 72 and regular; apex normal. Is this patient cured? Certainly not yet, for the tremor remains; he is still 20 lb. under his normal weight and has not recovered his full strength. He has refused to give up work and has neglected medical treatment for six months. While nine months of good medical treatment might have brought about equal improvement, he failed under the most favorable surroundings to gain weight until operation was performed. The contrast between his condition yesterday and ten months ago is most striking.

Case IV. Surgeon, Von Mikulicz. Woman of twenty-one; entered the Massachusetts General Hospital in April, 1902. Two and a half years previous became nervous and excitable, palpitation, profuse sweating, and right eye was prominent. Two years ago goiter developed with dyspnea on exertion. At entrance pulse was 156; cardiac enlargement; fine tremor of hands; marked pigmentation of skin. Under neutral bromide of quinine and rest in bed, patient improved and was discharged in six weeks feeling much better. A year later, in May, 1903, in spite of continuous treatment with bromide of quinine, patient re-entered hospital in about the same condition as at first: profuse sweating, insomnia, extreme nervousness, but pulse was only 124. Operation by Professor Von Mikulicz. Upper

part of left lobe removed; superior and inferior arteries tied on the right. Stormy convalescence with very high pulse and temperature. Two weeks later, however, patient feels much better; eyes less prominent, pulse regular, rate 120. Three years later recurrence of symptoms; half of right lobe removed; again much improved by operation, but at the present time, in spite of more or less continuous medical treatment, the left lobe has hypertrophied and the patient still presents some symptoms of the disease.

Turning for a moment to the medical statistics, we find reports in 1908 by Jackson and Mead of 85 cases treated with Forcheimer's neutral bromide of quinine. Of these 85 cases, 29 reported by letter; 56 were personally examined. Of the 29 cases, 20 regarded themselves as well, 7 were unimproved and 2 were dead. Of the 56 examined, 42 showed no obvious signs of the disease after two years, 7 were improved, 6 unimproved. Sixty-nine per cent of the 29 cases considered themselves well; 75% of the 56 cases appeared well at the time of examination. Under 2% died. These are most excellent results, but it must be remembered that these patients were almost all ambulatory cases.

In December, 1909, Rogers and Beebe reported the results of their specific serum treatment in 480 cases of all stages of Graves' disease: 15% cured; 10% no subjective symptoms; 50% improved, that is, after a few months of treatment, patients disappeared; 17% unimproved; 8% dead. These results are by no means as favorable as Jackson's treatment with bromide of quinine, but the mortality suggests a severer grade of the disease, and some patients with early acute toxemia showed marked improvement, which had not taken place under the usual treatment.

How shall the physician decide which cases shall be treated medically and which subjected to operation? In this borderland disease, close cooperation between the physician and surgeon is necessary to accomplish the best results. Medical treatment should always be tried first, its duration to depend upon the degree of improvement and upon the circumstances of the patient as regards ability to rest. In the poorer classes, operation, in spite of its dangers, should be done earlier, as it offers hope of quicker improvement. When tumors are present in the gland, operation should be done early in a quiescent period. Relapsing cases should probably be operated upon; if each succeeding relapse leaves the patient at a lower level, surgery is indicated before chronic myocardial and vascular degenerations make the case incurable. Severe chronic exophthalmos is an indication for operation. In very acute Graves' disease, after the usual treatment, Rogers' serum, if obtainable, should be used. If no improvement takes place shortly, a minor operation under cocaine with ligature of arteries or veins should be done in the majority of cases. If the patient survives the operation, some of the most brilliant surgical results follow in these cases. In estimating the risk of operation, it must be remembered that in these hyperacute cases conservative treatment gives its greatest mortality.

In spite of Kocher's extensive experience and low mortality, 3.5%, most of the operations being done under cocaine anesthesia, the majority of surgeons have come to prefer general anesthesia with ether.

Crile is convinced that the psychic factor, the dread of operation, is in a great measure responsible for post-operative hyperthyroidism. This may explain the deaths following minor operations, such as ligature of the vessels. Whether it is necessary to keep the patient in ignorance of the operation for several days, and then after narcotics to operate practically without the patient's knowledge, is open to question. No such measures are taken at the Mayo clinic, where the mortality is as low as 4%.

I regard one to three weeks of absolute rest in bed, with appropriate treatment, as the most important preliminary to operation in these cases, and, so far as possible, the psychic element must be considered. In planning the amount to be done at operation, the surgeon must remember that he is attempting to modify the function of an overactive gland; that several operations may be necessary; that it is far safer to do too little than too much. Simple ligature of the vessels, arteries, veins or both, is often all that is necessary in some of the milder cases and is all that the hyperacute cases will usually bear. Ligature of one or both superior thyroids is quicker and easier than the inferior thyroids. The ligature, always of silk, must be placed close to the capsule of the gland in order to avoid the blood supply of the parathyroid bodies. If the patient improves after this preliminary operation, partial thyroidectomy may be undertaken with increased safety at a later period.

In discussing the technic of operation I shall mention only a few points. The reversed Trendelenburg position markedly diminishes venous bleeding. The transverse low necklace incision gives adequate exposure and leaves a minimum scar. The anterior muscles should be divided at a different level and carefully sutured at the end of the operation. The gland should be handled with extreme gentleness; one is surprised at the thinness of its proper capsule, which should be brushed back by dry sponging, carrying with it the parathyroid glands, which are rarely seen. In primary Graves' disease the gland is extremely vascular. Great care must be taken to avoid hemorrhage, and hemostasis must be absolute. More reaction usually follows removal of half of one lobe than half of the gland, due probably to the crushed thyroid tissue left behind. It has seemed to me to be of advantage, after hemithyroidectomy, to tie the superior vessels on the other side. The wound should always be drained by a stab below the original incision, which should be entirely closed. The scar is slight and inconspicuous. After operation, salt solution should be freely given by the different methods in an attempt to diminish post-operative hyperthyroidism. Hoarseness often persists for some time; occasionally it is perma-

nent, but is then usually due to an injury of the recurrent laryngeal nerve. If only one side is paralyzed, a relatively good voice is usually acquired.

In spite of the relatively small mortality, as gathered from the larger statistics of Kocher, Mayo and others, I cannot but consider the operation for acute Graves' disease a dangerous one, only to be undertaken by a skillful surgeon. It is of great importance that proper medical treatment be continued for a long time after operation; in fact, it seems to me that the benefits of surgery are often lost from the belief of the patient, partly fostered by the attitude of the surgeon, that operation alone will cure Graves' disease.

Finally, in conclusion, it seems to me that it is of utmost importance that the physician recognize that surgery, in properly selected cases, offers more and quicker improvement than medical treatment. To be successful, earlier operation must become the rule before incurable degenerations have developed. When reasonable medical treatment has been carried out, the surgeon should be consulted. While from the very nature of the disease *permanent cures* may not be common, *permanent improvements* follow timely and appropriate operation in the large majority of cases after medical treatment has proved unavailing.

DISCUSSION.

Dr. J. M. Jackson, of Boston: I have to speak just for a few minutes on some indications for operation in exophthalmic goiter, a little more fully perhaps than Dr. Porter reported to you. In following perhaps 250 cases of exophthalmic goiter, I feel that one of the most important indications is the loss in the condition of the myocardium. All these cases, if allowed to go on sufficiently long, sooner or later must develop a certain amount, more or less, of myocarditis. Now if we are going to cure these patients we must get at them before that condition of the myocardium comes on. That is why I feel that we ought to call in the surgeon earlier than we have hitherto. Although I recognize perfectly well that from 25 to 50% of cases get well without treatment, or with very simple treatment, at the same time I think we give our patients the best chance if we take them before it develops into weakness of the heart wall itself. Moreover, if we find when a patient comes to us that she has already a myocarditis, she should be operated on at once. I mean by that, if she shows any irregularity of pulse either of rate or rhythm, or if we find any enlargement or dilatation of the heart, — those cases should be done at once. Of course, I do not feel that we can cure all those cases; because once a myocarditis is established, the chances are that it cannot be checked, but operation does prolong life and helps the general condition. So that I do not feel the complication of heart trouble to be an argument against operation.

There is a class of cases I have been interested in of late: Several times I have seen these patients and could not account for the symptoms — dyspnea and bronchitis with wheezing and discomfort in breathing. Examination of the throat showed no signs whatever of enlargement of the thyroid, and yet with the x-ray and by percussion I have found a thyroid running well down into the chest, and at operation have seen a thyroid as large as my fist which was being dug out from below the clavicle. These must occasion a good many of the cases of sudden death. I have seen three cases already where the patients died suddenly — there was an enlargement of the thyroid which had not been recognized.

Then one more point in connection with the thymus. The persistent thymus gland is supposed to be a complication of operation, but although I have seen several cases in which the thymus gland was present, and have advised against operation, I am inclined now to feel I would do better to advise operation in those cases, because it is impossible for us to say whether the case is one of persistent thymus or whether it is a normal thymus and a bunch of fat; and I feel very strongly they had better take their chances of sudden death and have the operation than to go on and have the same advanced symptoms of exophthalmic goiter. I feel that the combined effort of surgical and medical men is nowhere so important as in these cases of exophthalmic goiter. It is not a medical disease nor a surgical disease, but a combined disease. I think the sooner we get together on it and work this out, the better statistics we shall have. I do not feel that our statistics thus far amount to anything. We say, "a patient is cured." We ought to say, "cured to date," because we do not know when any one may relapse. I have seen a case for fifteen years absolutely free from symptoms which has to-day developed an acute exophthalmic goiter. So we shall have to change our nomenclature, and if we say "cured," will say "cured to date."

Dr. J. C. Munro, of Boston: It pleases me to hear Dr. Jackson advise that surgical and medical men get together on these cases. We must get together. There are a certain number of cases easily cured by medical treatment, and also a certain proportion easily cured by surgery, and some the surgical and medical men have got to work out together. Personally I still feel afraid of exophthalmic goiter; our cases have been advanced cases — I seem to feel we have not had enough experience yet or worked enough with medical men to know which cases will stand operation and which will not.

Dr. F. B. Lund, of Boston: I would like to emphasize one or two points in Dr. Porter's paper. One is the fact that from the multifarious character of the disease, and the various degenerations and connections it has made, statistics are very hard to establish. I have had a certain small experience in operating and my cases have all been light ones, and I don't think there is much danger of their getting to the surgeon without a good deal of medical treatment. It requires much judgment to tell just how much thyroid to take out, or in which cases one ought not to take out any thyroid but ligate the vessels; and I have had admirable results in ligating the vessels. I think Dr. Porter is modest about reporting his case as cured. I think if a case gets so much better as that he reported, I should say he was perfectly well. Of course, you cannot make a man younger by any operation.

I think these patients have been neglected, misunderstood; it is a class of patients with which we are going to accomplish a great deal.

DISTORTION OF THE FACE AND SKULL DUE TO CONTINUED FIXED POSTURE IN EARLY INFANCY.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

The following communication is made for the purpose of calling attention to the fact that the head in the first year or two of life is so soft and yielding that it can be molded almost at will and that, because of this, many of the deformities or peculiarities in the shape of the head which lead

to varying degrees of disfigurement later in life can easily be avoided if this fact is appreciated at this early period.

It has, of course, long been known that the shape of the head could to a certain extent be molded so as to conform to certain types, and for centuries certain tribes of Indians have been

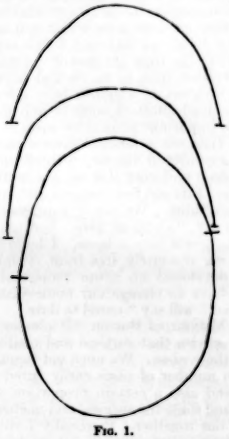

FIG. 1.

known by such peculiarities, which were the direct result of bandaging or compression of the head during infancy. That simply posture in bed, however, with nothing else to cause pressure other than the weight of the head, could cause peculiarities in the shape of the cranium had not been appreciated by the writer until the first case

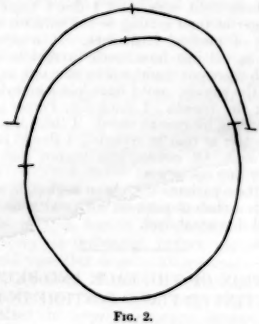

FIG. 2.

here reported was called to his attention. At that time he was unable to find any literature upon the subject, and the anxiety which he at first felt because of the magnitude of the deformity was shown later to have been wholly unnecessary. In this case also the distortion of the face as well as the vault of the cranium was strikingly noticeable, and by measurements both features were easily demonstrable. The rapidity with which the deformity was corrected by simply changing the position of the child as she lay in bed, with no mechanical appliance or other measure, surprised him and has been followed so commonly since by similar relief that brief mention of the subject seemed to him justifiable. Previous to this case he had supposed that while distortion of the sides or top of the cranium might occur, that the base of the skull was so firmly put together that only

FIG. 3.

considerable force could to any appreciable extent change its shape.

The case that first called the subject to the writer's attention was a child of four months, who was seen in consultation with Dr. J. B. Swift because of a peculiar facial distortion. The child was generally healthy and showed no evidence of rickets or disturbance of nutrition. As the result of the belief held by the nurse that to lie upon the left side would result in disease of the heart, the child had been kept almost continuously upon the right side, but aside from this there had been

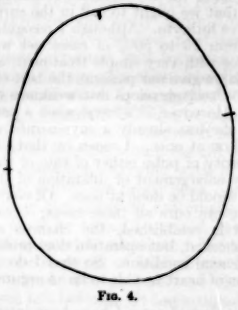

FIG. 4.

nothing peculiar in the care that the child had received. The tracings of the head taken at that time are shown in Fig. 1 and were made by passing a flexible lead around the head, over the frontal eminence of the frontal bone and just above the ears to the occiput. The anterior part of the ear, or the point just above the external auditory meatus, was marked and is the point on the sides indicated in the tracings. No attempt was made

to record the distortion of the cranial vault, but the degree of twist of the basal part of the skull is shown clearly. The later tracings, the first taken two months and the other three months after the first, show how completely the correction of the distortion had been from doing nothing other than to have the child kept continuously upon the other side. After that the position was naturally changed regularly.

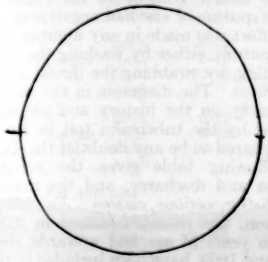

Fig. 5.

Since this first case was seen, many others have been seen by the writer, and as the result of this experience it is evident that the position in which the child is kept during these early months of life determines to a large extent the shape of the head.

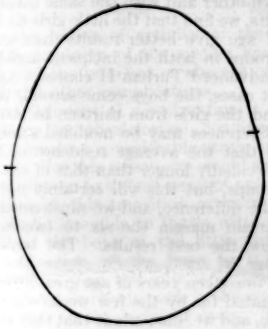

Fig. 6.

As is shown by the following tracings, the round head, the flat head and the twisted head can be made almost at will, and once the condition is appreciated it is possible to tell almost to a certainty from the tracing alone the position in which the child has been kept when lying down.

That these conditions exist, and exist quite commonly, there can be no question from the results of observations made upon quite a large number of individuals, and that the condition is not seen more often in adult life is probably largely due to the fact that as soon as the child is old enough to be able to move about and change its position, voluntarily the distortion corrects itself. That this is not always the case is at once apparent in studying the tracings of the head made by the hatters, where a surprising variety of types will be found, and it is also shown by some of the tracings here presented of persons older than infants. The type of these distortions is so similar to those seen in early life where the condition is wholly due to posture that it seems probable that many of these peculiar-shaped heads are of this origin and are not congenital, as has often been supposed.

The following cases are used to illustrate the points here mentioned:

Case I. A girl baby, a patient of Dr. J. B. Swift, four months old. Had been a healthy baby with no signs of rickets or malnutrition. Had been kept continuously upon the right side, so that the weight of the head was received upon the right side a little back of the ear. The shape of the head when first seen was as is shown in the inner tracing of Fig. 1. The child was turned upon the other side, and about two months later the condition was as is shown in the middle tracing, while in another month the head was normal, as is shown in the outer tracing.

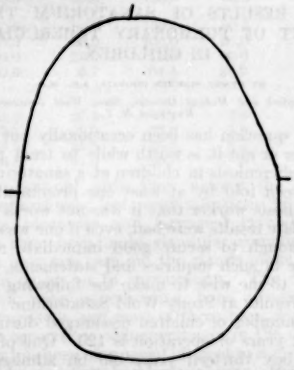

Fig. 7.

In this case, with the distortion of the base of the skull there was a natural distortion of the face, the whole right side, the frontal eminence, the malar bone and the superior maxilla being so much more anterior than the left side as to give a strange and most unnatural expression. With the improvement in the cranial distortion, as shown by the tracing, the facial distortion also disappeared. The child has remained well now for some years without showing peculiarities of anything other than good health.

Case II. A boy child of five months who had been kept continuously upon the right side for several weeks previous to the examination because of a painful left arm following vaccination. The child was generally well and showed no signs of rachitis. With simple change of position the shape was corrected so that in six months the distortion which in the beginning was as is shown by the inner tracing of Fig. 2 became as shown by the outer tracing.

The other observations made by the writer are similar to these. The following illustrations are presented to still further emphasize the types:

Fig. 3 is of a girl child of five months who had lain continuously upon the left side, the distortion being the reverse of that shown in the previous illustrations.

Fig. 4 is of a boy of fifteen months who had always lain upon the left side of the face and shows a similar condition to that of Figs. 1 and 2, except that the right posterior side of the head is more rounded.

Fig. 5 is from a boy of two years who had during the first year of life been kept almost continuously upon the back.

Fig. 6 is of a boy of seven, and Fig. 7 is of a woman of thirty-three years, the tracings being presented to show how similar these peculiarities which are seen in the older children and adults are to those seen in infancy, and suggest naturally a similar cause.

Clinical Department.

SOME RESULTS OF SANATORIUM TREATMENT OF PULMONARY TUBERCULOSIS IN CHILDREN.

BY HENRY SKINNER GOODALL, A.B., M.D.,

Superintendent and Medical Director, Stony Wold Sanatorium, Lake Kushaqua, N. Y.

THE question has been occasionally put to me whether or not it is worth while to treat pulmonary tuberculosis in children at a sanatorium. I have been told by at least one prominent antituberculosis worker that it was not worth while, as the late results were bad, even if one was fortunate enough to secure good immediate results. Because of such inquiries and statements, it has seemed to me wise to make the following report of our results at Stony Wold Sanatorium.

The number of children discharged during our first six years of operation is 120. One of them was a boy thirteen years old on admission, a moderately advanced Turban II case, who was discharged with disease arrested. One case was non-tubercular, one remained with us only two days, one was a laryngeal case, with only very slight demonstrable pulmonary disease, and five had some enlargement of the lymphatic glands without suppuration and without positive signs of involvement of the lungs. One of the glandular cases was discharged apparently perfectly well, and the others were much improved. The laryngeal case had considerable ulceration of the epiglottis, but was discharged in good condition with the ulcerations healed. He has, however, since died.

The remaining 111 children comprise 33 boys between the ages of six and twelve inclusive; 35 girls between the ages of six and twelve inclusive; and 43 girls between the ages of thirteen and sixteen inclusive.

The classification of the National Association for the Study and Prevention of Tuberculosis was followed, the terms used being interpreted according to the definitions approved by the American Sanatorium Association. The presence of râles of any kind was considered incompatible with apparent cure, except in case of transient fine dry crackles at the base of the axilla, and those râles also were considered incompatible with apparent cure if the region where they were heard had shown evidence of pulmonary disease during residence.

It will be noticed that the presence or absence of tubercle bacilli in the sputum has been omitted from the table. Almost all the children either raised no sputum or else had negative sputum. No special effort was made in any number of cases to obtain sputum, either by washing the stomach in the morning, by swabbing the throat after cough, or otherwise. The diagnosis in the children was based chiefly on the history and physical signs, supported by the tuberculin test in cases where there appeared to be any doubt of the diagnosis.

The following table gives the condition on admission and discharge, and the average residence of the various classes. For purposes of comparison, the results obtained in 235 adults, seventeen years of age and upwards, discharged in 1908 and 1909, have been included in the table.

It will be observed that the number of patients in all classes of children, except the incipient and moderately advanced Turban II, is much too small to give averages of value. We will, therefore, limit our comparisons to these two classes, which embrace the great majority of the children. Comparing the classes in the different age-groups with each other and with the same classes among the adults, we find that the little girls six to twelve years of age give better results than any of the other groups in both the incipient and the moderately advanced Turban II classes. Among the incipient cases, the boys come second, the adults third and the girls from thirteen to sixteen last. These differences may be modified somewhat by the fact that the average residence of the little girls is decidedly longer than that of either of the other groups, but this will certainly not account for all the difference, and we must conclude that by a certain margin the six to twelve-year-old girls show the best results. The boys show a percentage of good results above the girls of thirteen to sixteen years of age greater than could be accounted for by the few weeks' difference in residence, and we must admit that they come next to the little girls. The girls from thirteen to sixteen give poorer results than either of the other age-groups of children, and worse than those obtained among the adults, and this in spite of the fact that the average residence of the thirteen to sixteen-year-old girls is much greater than that of the adults.

Among the moderately advanced Turban II cases, making due allowance for differing average of residence, the little girls six to twelve years old again give the best results, the girls from thirteen to sixteen years come next, the boys from six to twelve years third, and the adults last. Taking all classes together, the order is little girls, little boys, girls thirteen to sixteen years old and adults.

The reasons for these differences may be sought for in the presence or absence of the menstrual

function, the habits of activity of the various groups, the condition of the system apart from the lungs and the presence or absence of gastro-intestinal and other complications.

The establishment of menstruation is a period of unbalance in physiological conditions, and frequently involves considerable strain upon the vital forces. For this reason, we would expect the girls from thirteen to sixteen years of age, who are passing through this transition or have recently done so, to be less able to battle with a serious disease than the boys or the little girls. The natural inclination of the boys to take more violent exercise than the girls is a handicap to them and shows its effects more in the moderately advanced than in the incipient cases. We have very little trouble in keeping the girls of all ages reasonably quiet, but the boys will be boys whenever they can get out of sight of the doctors and nurses, much to their detriment.

The functional condition of the various organs, aside from the lungs, has been much better, on the average, among the little girls and the boys than among either of the other groups, and better among the thirteen to sixteen-year-old girls than among the adults. There are fewer and less severe gastro-intestinal disorders, fewer cases of appendicitis, of tubo-ovarian disease, dysmenorrhea, etc., of renal disturbance and of neurasthenia. There is usually no worry over family or financial matters to hold the little ones back. There have been less tubercular complications among the little girls and boys and among the thirteen to sixteen-year-old girls than among the adults; less hemorrhages, less mixed infections, less pneumonias, pleuresies and laryngeal involvements. There have been more glandular complications, but in only one case did the glands make serious trouble or go on to suppuration. The cases of children with complicating bone disease have been very few, and most of them have done well.

The occurrence of hemorrhages in the different groups has been of especial interest to me. Among the 33 boys, only 2 had hemorrhages either before or during residence. Among the 35 little girls six to twelve years old, only 5 had hemorrhages before or during residence, and 3 of these 5 girls began to menstruate within a short time (two or three months) after the hemorrhage. Of 43 girls thirteen to sixteen years old, 15 had hemorrhages before or during residence, and all of these but 3 had established menstruation before the hemorrhage or did establish it soon after. Two of these three were old enough and sufficiently developed so that they would undoubtedly have been menstruating but for the severity of the pulmonary disease.

The later results can be stated very briefly. So far as we have been able to trace the three age-groups of children, all who were discharged as apparently cured or arrested are at present as well as, or better than, they were on discharge. Making a liberal allowance for relapses, etc., among those not traced, we may still feel sure that the final results are as good as, or better than, those among our adult patients. Many of those

who have been traced and found to be still apparently well have established menstruation since discharge, and some have married and borne children.

The number of cases reported above is admitted to be rather small for the establishment of positive conclusions. The comparative results among the different classes on discharge have, however, been the same from year to year, and substantially the same as the aggregate results for all the years.

I believe, therefore, that we may safely conclude from our experience at Stony Wold Sanatorium, first, that the immediate results of sanatorium treatment of children afflicted with pulmonary tuberculosis are as good as, or better than, those obtained among adult women under the same conditions; and, second, that the final results will prove to be at least as good as among our adult patients.

Children are accordingly entitled to the same opportunity to enjoy the benefits of sanatorium treatment as are the adults, and greater provision should be made at once throughout our country to afford them such treatment.

CONGENITAL STENOSIS OF THE PYLORUS. THE REPORT OF THREE SUCCESSFUL CASES FOLLOWING GASTROJEJUNOSTOMY. REMARKS.

BY CHARLES L. SCUDDER, M.D., BOSTON,

Surgeon to the Massachusetts General Hospital; Lecturer on Surgery at Harvard Medical School.

I WISH to report here three hitherto unrecorded cases of pyloric stenosis in infants:

CASE VI in author's series. R. J. M. The patient was a boy baby five weeks old, under the care of Dr. Elam, of Gardner, Mass., and Dr. John L. Morse, of Boston. The date of birth was Dec. 14, 1908. The baby weighed 6 lb. He nursed and seemed perfectly well for three weeks.

When three weeks old the baby began to spit up a little milk. Vomiting about an hour after each feeding then became frequent. The weight of the baby at this time was 7 lb. 12 oz. During the ten days before operation he lost ½ lb. The bowels were constipated. The movements were dark green, with an occasional curd. The character of the vomiting was explosive. The material vomited consisted of the food taken by the baby. At no time did the vomitus contain bile.

Upon examination the baby looked a little peaked, but seemed to be in good condition. A pyloric tumor was easily felt. Upon introducing into the stomach about 2½ oz. of water there was very marked visible peristalsis. On Jan. 22, 1909, a posterior gastro-enterostomy was done. The pyloric tumor was palpated and found to be the size of the end of the thumb, the tissue about it translucent-like and glistening.

The baby recovered well from the operation, gaining from ¾ to 1 lb. in weight each week. He was troubled for a considerable time after the operation with a little spitting up of milk, but this gradually ceased. The baby is now perfectly well and strong. May 18, 1910, he weighed 21 lb. at the age of one year and five months.

CASE VII in author's series. D. C. N. H., Jr. A patient of Drs. Morse, Swain and Dunn, of Boston. A boy baby eleven weeks and four days old. The child was born June 3, 1909, after a normal confinement. The weight at birth was 9 lb. The baby nursed and seemed to be perfectly well during the first six weeks of its life, reaching a weight of 10 lb. 10 oz.

At this time there was a sudden onset of vomiting. There was no fever and the movements were normal. A whole feeding or several feedings would be retained and then vomiting would begin again. Artificial feeding was immediately instituted, but the child lost in weight and strength and there was no abatement of the vomiting. The movements were normal except for an occasional small, watery and dark-green dejection. The child was always willing to take food. The vomiting was explosive. The material vomited was usually the whole of a feeding. The vomitus at times contained specks of bile. The weight had decreased to 8 lb. 12 oz.

Upon examination the tongue was found to be clean and the mouth healthy. The abdomen was sunken and there was visible gastric peristalsis. A pyloric tumor was distinctly palpable. The stools were meconium-like.

Aug. 25, 1909, a posterior gastro-enterostomy was done. Recovery from the operation was without incident. The child gained steadily in weight and has remained perfectly well. He is now one year old and weighs over 20 lb.

CASE VIII in author's series. W. F. H., Jr. The patient was a boy baby four weeks and four days old, under the care of Dr. Straw, of Manchester, N. H., and Dr. John L. Morse, of Boston. The child was born March 20, 1910, and weighed 7½ lb. The baby nursed and seemed perfectly normal for the first sixteen days of its life.

On April 5, 1910, the baby began to vomit. For the next two weeks he was fed a mixture of whey and modified milk every two hours. He had occasional cyanotic attacks.

Upon examination classical symptoms of pyloric obstruction were present. The stomach was dilated, the bowel collapsed. The movements were meconium-like. A pyloric tumor was readily palpated. There was a marked thinness of the body, and the general condition was poor.

April 22, 1910, a posterior gastro-enterostomy was done. The child recovered from the anesthetic satisfactorily and took within the first hour 1½ dr. of milk and retained it. The first days following the operation there was difficulty in keeping the baby alive. He was so feeble that for one twenty-four hours life seemed to be fast fading away. Warm water bottles, no bathing, moderate stimulation, judicious feeding, salt solution and castor oil together placed the baby on a living basis. When two months old he had gained almost his birth weight, looked well, was strong and improving rapidly. He is gaining an average of an ounce each day. To-day, July 9, 1910, the baby is three months old, weighs 9 lb. 13 oz. and is in perfect health.

REMARKS.

These three cases reported by me for the first time are, respectively, the sixth, seventh and eighth consecutive successful cases of congenital stenosis of the pylorus following gastrojejunostomy. In the BOSTON MEDICAL AND SURGICAL JOURNAL of March 4, 1909, I reported a fifth successful case.

These three latter cases illustrate certain important facts concerning pyloric stenosis in infancy. All these cases were boys. They were apparently well babies when born. They were all

breast-fed babies. Case VI was well for the first three weeks of his life. Case VII was well for the first six weeks of his life. Case VIII was well for the first two weeks and two days of his life. The first sign that anything was wrong with these babies was the appearance of vomiting. Associated with the continual and periodical vomiting there was a loss in weight. The baby ceased to gain its normal increment in body weight. Experiments in each case in feeding the baby were carefully made. The several changes in food were only of temporary benefit. In all three cases a pyloric tumor could be felt.

The unexpected persistence of vomiting in a boy baby within three weeks of birth, in a boy baby who has been nursed by his mother, a continuous loss of weight despite careful feeding, the presence of a palpable pyloric tumor, visible gastric peristalsis, — these are important signs pointing to an obstruction at the pyloric orifice of the stomach.

These signs and symptoms should immediately arouse the suspicion that treatment of the obstruction by diet and mechanical measures are inefficient. The moment that the diagnosis of pyloric obstruction in infancy is made, surgical treatment should be instituted.

It is the aim of the surgeon to avoid operating for a diagnosis. I believe, however, that in certain of the very doubtful cases of pyloric stenosis in infancy it may be wise to do an exploratory operation when the delay in operating would sacrifice the child. It is better to occasionally do a comparatively safe exploratory operation when the child is in excellent condition and find no lesion at the pylorus requiring surgical treatment than to postpone the operation and allow the child to die from unrelieved obstruction because of delay. For there comes a time in the life of these little babies when operative interference, even under the best conditions, is not borne well, and if the child is allowed to go along upon medical treatment, and is continually losing ground, even though the diagnosis is not certain, there will come a time when even the surgeon can do nothing to save the child. Operation, I believe, should be done when the diagnosis of pyloric stenosis is made, and in doubtful cases when skilled medical treatment of perhaps two weeks' time has been tried and found unavailing.

It must be borne in mind that two objects are sought by operation: (1) The overcoming of obstruction to meet the emergency of starvation, and (2) the restoration by operation of the gastro-intestinal canal so that it will serve the individual during the remainder of his life.

The medical practitioner who ordinarily comes into contact with these cases at the very beginning of the symptoms must, I believe most emphatically, recognize the fact that delay in operating upon these little babies with true tumor stenosis is largely the reason for the present surgical mortality. The operative treatment when the baby is first taken ill is attended by comparatively slight risk. The risk of operating is less than the risk of unskilled medical experimenting with foods and drugs. Skilled feeding may be wise in doubtful cases for two weeks, but for no longer.

Early operation upon little babies who have a stenosis at the pylorus is the best and safest treatment.

A CASE OF HEMORRHAGE OF THE NEWBORN TREATED BY DIRECT TRANSFUSION: RECOVERY.

BY F. S. NEWELL, M.D., BOSTON.

This case is reported because it is of sufficient rarity to warrant the report of all cases, whether the outcome is favorable or unfavorable, in order to add to the scanty literature on the subject. No attempt will be made in this report to draw elaborate conclusions as to the future usefulness of the treatment or to collect reported cases from the literature, but the case is reported simply as one of interest.

The patient was an apparently healthy female child, twenty-four hours old; was the second child of healthy parents, and weighed at birth 7 lb. 6 oz.

Examination showed it to be normal in every respect, and it seemed perfectly well up to twenty-four hours after birth, when it vomited a small amount of bright blood, perhaps a half ounce in all. No further bleeding occurred until three hours later, and it seemed as if this might be the single hemorrhage which had stopped spontaneously. At 8.30 P.M. April 9 a second hemorrhage occurred and the baby vomited about 2 oz. of bright blood. Dr. John L. Morse was asked to see the baby in consultation, and preparation was made for a transfusion, if he should agree with the treatment. Before he saw the patient at 9.30 P.M. two other hemorrhages of moderate amount had occurred and the baby had one large movement of meconium mixed with blood.

Examination showed the baby to be somewhat pale, but in apparently good condition, the pulse ranging between 130 and 135. It seemed probable that the hemorrhages would not stop spontaneously and that whatever was going to be done had better be done while the baby was in as good condition as possible. The advisability of trying to stop the hemorrhages by the subcutaneous injection of rabbit serum was discussed, but it was decided that direct transfusion offered the greatest hope. This operation was, therefore, decided on and was performed by Dr. J. C. Hubbard, the baby's father acting as donor. The operation presented considerable difficulty owing to the small size of the veins of the patient. The left popliteal vein was first exposed, but it was found to be too small to permit union with the father's radial artery. The internal saphenous vein was then dissected out and with considerable difficulty union was secured, the Elsberg canula being employed. The connection between the vessels was allowed to persist for twenty-five minutes, and the wounds closed with interrupted sutures and dressed with sterile dressing. During the transfusion the baby had three large movements containing old and bright blood, but from this time on no further bleeding occurred.

The operation was difficult and it was two hours before the connection of the vessels was obtained. The baby was in a much improved condition at the end of the transfusion, the color being better and the pulse of better character. The following day the temperature was 103 and the pulse 120, the baby seemed weak and listless, but otherwise in satisfactory condition

The temperature gradually dropped to normal on the third day after the operation, and the baby showed steady signs of improvement. By Dr. Morse's advice it was put on whey and given small amounts at frequent intervals, gradually increasing in amount and strength until at the end of three weeks a full-strength milk-whey mixture was being used. The baby did not regain its birth weight until two and a half weeks after the transfusion, and apparently did not start to gain for a week from the time of operation, but from that time on its gain was steady and rapid. It was discharged from the hospital five weeks after delivery, weighing 9 lb. The wounds were extremely difficult to keep clean, particularly the one in the groin, and union was delayed, although no suppuration took place. There was at no time any milk in the mother's breasts, and, therefore, the feeding was entirely artificial.

The case illustrates two points: First, the extreme difficulty of performing a transfusion on a newborn baby on account of its small-sized vessels, and, second, the prompt checking of the hemorrhage as soon as the effect of the donor's blood became noticeable. The good result was due in no small part to the extreme faithfulness and care of the nurse who had charge of the baby, as it was extremely difficult to keep the wounds from being constantly contaminated by urine and feces.

In conjunction with the cases previously reported, it seems evident that the early cases of hemorrhage of the newborn can be successfully treated by the transfusion method. On the other hand, the results have been unfavorable in the late cases of hemorrhage, i. e., those occurring after the first week. This points to a difference in the etiology of the two conditions and suggests that in the late cases some septic process may be at the bottom of the trouble, and in which case transfusion cannot be expected to be successful. Judging from the difficulty of the operation, I believe that transfusion in infants should always be performed by an expert, if possible, and certainly should not be attempted by the general practitioner, except as a last resort, even if he is surgically inclined, since the margin of safety is so small that the increased exhaustion caused by a bungling transfusion may take away what chance the baby has.

OVARIAN CYSTS WITH TWISTED PEDICLES.

BY F. W. JOHNSON, M.D.,
Gynecologist-in-Chief, Carney Hospital.

I HAVE had four cases of this kind during the winter. One was in a woman sixty years of age. A small cyst of the right ovary became twisted three times on its axis. Although this did not completely shut off the blood supply to the tumor, yet it did so to such an extent that the tumor had become adherent to the omentum, a small coil of intestine and the parietal peritoneum. Constant pain, which was in the right side on a level with the umbilicus in the region of the tumor, necessitated her seeking relief.

The second case was in a woman forty-three years of age. In addition to the ovarian cyst she had a large fibroid. The ovarian cyst from the right side was as large as a good-sized grape fruit and was so twisted on its pedicle that it received its nourishment from omentum, intestines, liver and parietal peritoneum. At first the tumor was supposed to be from the liver, but after it was separated from its adhesions it was found to be a cystoma of the right ovary. The hemorrhage was profuse and was stopped only by covering the oozing surfaces with towels wrung out in boiling water.

The third case was in a woman forty-five years of age. The tumor evidently became twisted two years ago when she had an attack of peritonitis, followed by a long illness, during which there were repeated chills and elevation of temperature. When I saw her there was no fever, but there was emaciation and constant pain in the left lower quadrant of the abdomen. I expected to find an ovarian cyst which had become tubercular or malignant. On opening the abdomen, a cyst from the left side, as large as a child's head, with twisted pedicle, was found adherent to parietal peritoneum and intestines. After a great deal of difficulty the cyst was removed without rupture. It contained nothing except pus.

The fourth case was seen in consultation with Dr. Thomas B. McQuaid, of Everett. She was three months pregnant and had had severe pain and soreness just to the left and a little below the umbilicus for four days. On the morning of the fourth day the pain was so severe that she fainted. Her temperature was 100, her pulse 120 and there was evidently a localized peritonitis in the left lower quadrant of the abdomen. On examination the pregnant uterus could easily be made out. To the left of it was an indistinct movable mass. A diagnosis was made of an ovarian cyst with twisted pedicle. On opening the abdominal cavity considerable turbid fluid was found. The cyst, which was the size, shape and almost as dark in color as an egg plant, was adherent to the parietal peritoneum and omentum by recent adhesions. The tumor had become completely twisted off at the junction of pedicle and tumor. There was and had been no bleeding. The stump near the tumor looked as if it might have been crushed off by an instrument. The only communication between the tumor and the left ovary was a shred of tissue the size of a cod line. The operation was followed by recovery without producing an abortion.

Medical Progress.

REPORT OF PROGRESS IN OTOLOGY.

BY HARRIS PEYTON MOSHER, M.D., BOSTON.

(Continued from No. 10, p. 407.)

NYSTAGMUS.

NYSTAGMUS is the name applied to any oscillating movement of the eyeballs. It is almost always reflex and involuntary. There are two classes of nystagmus, undulating and rhythmical nystagmus. Rhythmical nystagmus is the kind which is mostly associated with ear diseases.

Rhythmical nystagmus consists of two movements, a rapid and a slow movement. The rapid movement or component may be in any direction, though usually it is either to the right or to the left. The slow movement occurs in the opposite direction. The direction of the quick component is used to name the form of the nystagmus. Nystagmus, therefore, is designated as nystagmus to the right if the quick movement is to the right. Further, nystagmus is called horizontal if the plane of the movement lies in or is parallel with a second plane passing hori-

zontally through the pupils of both eyes. Vertical nystagmus occurs in a direction at right angles to the horizontal plane. There is also oblique nystagmus. This occurs in a plane to the right or to the left of the vertical axis of the body. Finally, there is rotary nystagmus. In this the eye tends to revolve in the axis of a line drawn straight backward through the pupil as a spool can be made to turn on a lead pencil.

Ewald's experiments on pigeons established the following facts: (*a*) Excitation of a single canal can produce nystagmus only in a plane corresponding to the plane of the canal. (*b*) By reverse movements of the endolymph in any single canal there is produced a reversal of the direction of the induced nystagmus. (*c*) The strongest nystagmus which can be produced by the irritation of a single canal is always in the direction of the ear experimented upon.

Remembering that the direction of the vestibular nystagmus takes its name from the direction of the quick eye movement, and that the gradual head and eye movements produced by Ewald in his experiments upon animals correspond to the slow component of vestibular nystagmus, Ewald's results interpreted for man would read as follows: Nystagmus induced by endolymph displacement in any particular canal is in a plane parallel with the plane of that canal, and in the direction opposite to that of the endolymph displacement.

THE CHARACTER OF VESTIBULAR NYSTAGMUS.

Vestibular nystagmus has the following characteristics:

(1) It has a quick movement in one direction and a slow movement in the opposite direction.

(2) It is increased usually in rapidity and always in length of excursion when the eyes are turned voluntarily in the direction of the quick movement.

(3) It becomes weak or may disappear wholly when the eyes are turned in the direction of the slow nystagmic movement.

Vestibular nystagmus always has these characteristics, whether produced by experimental irritation or by disease.

Vestibular nystagmus may be horizontal, oblique, vertical or rotary.

The nystagmus of acute labyrinthine disease is almost always rotary.

Nystagmus may be produced by pressure, by galvanism, by injecting hot or cold water into the canal and by turning.

NYSTAGMUS FROM PRESSURE.

Nystagmus can be produced by compression or exhaustion of the air in the external canal, or even by pressure on the tragus in cases of labyrinthine suppuration. It can be produced by direct pressure on the stapes. The movements in many cases are small and in others wanting. There is no uniformity in the results obtained from pressure nystagmus, and the method has little value except in the examination of cases of suspected openings in the semicircular canals.

GALVANIC NYSTAGMUS.

If the anode or the positive pole of a galvanic battery, armed with a small electrode, is placed upon the right tragus, and the kathode, or the negative pole, armed with a large electrode, is held in the hand of the patient during the passage of twenty milliamperes of current, nystagmus can be easily produced. This will consist in a quick rolling movement of the eyes to the opposite or unstimulated side and a slow return to the right side, or the side of stimulation. The nystagmus, however, will be observed only with a glance to the extreme left (in the direction of the quick movement) and not when the glance is straight ahead or to the right. It will not be a pure rotary nystagmus, but mixed with this movement there will be a slight horizontal element.

If, now, the electrodes are transposed, the results will be reversed. By comparing the results (see below) obtained with the use of heat or cold, it is found that the anode or the positive pole has the same effect as syringing the ear with cold water, and the kathode or the negative pole has the same effect as syringing with hot water.

If the patient is placed in the Romberg position, that is, standing with the eyes closed and the feet together, and the galvanic reaction is produced, the patient with nystagmus to the left falls to the right; with nystagmus to the right, the patient falls to the left. In other words, the fall is in the direction of the slow component of the nystagmus. Turning the head about a vertical axis either to the right or to the left will cause a fall forward or backward according as the slow component of the nystagmus is to the right or to the left. (Chamberlain.)

THE CALORIC REACTIONS.

(1) If the ear of a normal person is irrigated with water at the body temperature, no objective or subjective phenomena result.

(2) If the ear of a normal person is irrigated with water below the body temperature, the following signs of vestibular irritation are shown: (*a*) There is rotary nystagmus towards the ear not syringed. (*b*) The patient experiences vertigo. (*c*) The patient exhibits marked disturbances of equilibrium.

(3) If the ear of a patient is irrigated with water which is above the temperature of the blood, the same phenomena are produced, but with this difference. (*a*) The quick nystagmus movement is towards the ear irrigated.

BARANAY'S THEORY AS TO THE CAUSE OF THE CALORIC REACTIONS.

The whole labyrinth can be regarded as a vessel filled with fluid of the temperature of the blood. If cold or hot water is brought in contact with one side of this vessel, the specific gravity of the contained fluid which is nearest the exposed wall will be increased or diminished and the fluid at this point will rise or sink according

to the physical laws governing fluids of different specific gravity.

The parts of the semicircular canal system nearest the surface of the middle ear are: (1) The anterior part of the horizontal canal, (2) the external or ampullar third or the anterior vertical canal which points downward. Syringing the ear, therefore, with cold water would influence the temperature first at these points, With the head in the upright position, however. endolymph movement in the horizontal canal would be prevented by its horizontal position. On the other hand, sudden cooling of the ampullar end of the anterior vertical canal would, by condensation of the endolymph at this point, give rise to an endolymph movement downward towards its ampulla. That this experiment in normal persons is invariably followed by rotary nystagmus toward the opposite side is in exact accord with Ewald's experiments. The use of hot water, which, by reducing the specific gravity, would cause an endolymph movement in the opposite direction, invariably gives rise to a rotary nystagmus towards the ear irrigated. This is also in accord with the experiments of Ewald.

The value of these experiments lies in the fact that, when the vestibular apparatus has been destroyed either surgically or by disease, no reaction follows the application of either heat or cold. The caloric tests further are invaluable for determining the degree of impairment of the vestibular function.

THE ROTATION OR TURNING EXPERIMENT.

When a normal person is seated with his head erect and is turned upon a revolving chair and turned fairly rapidly for ten revolutions in either direction, say, for example, to the left, a horizontal nystagmus is set up with the quick eye movement in the direction in which the person is turned, i. e., to the left. When the turning is stopped suddenly, the quick eye movement changes to the right. The average duration of the nystagmus which follows this experiment is from forty to forty-five seconds.

THE EXPLANATION OF THE NYSTAGMUS CAUSED BY TURNING IN ACCORDANCE WITH EWALD'S EXPERIMENTS.

In order for turning in the horizontal direction to affect the fluid in any particular semicircular canal, that canal must lie in the horizontal plane. With the head erect the two horizontal canals lie in the horizontal plane. If the head is bent sharply forward or backward, the two superior vertical canals become for the time being horizontal. By turning the head, therefore, any of the three pairs of canals can be made to lie in the horizontal plane and can be tested separately. Suppose the head to be held upright and the individual to be turned in a vertical axis, and let the turning be to the right. The fluid in the horizontal semicircular canals, by reason of its inertia, at first lags behind, i. e., it suffers an initial displacement in the opposite direction. This initial endolymph displacement in the right horizontal canal is toward its ampulla, which in the left horizontal canal is toward the small end of the canal. According to the experiments of Ewald, these are the exact endolymph movements which in these canals cause nystagmus to the right. When, however, the rotations are suddenly stopped, there occurs again, by reason of its inertia, an endolymph displacement in the opposite direction, with the result that the direction of the nystagmus is reversed, i. e., rotation to the right is followed by nystagmus to the left.

RULES FOR DETERMINING THE FORMS OF NYSTAGMUS WHICH SHALL FOLLOW ROTATION.

Suppose the subject experimented upon to be sitting erect upon a revolving chair and to be revolved. His body revolves in a vertical axis. Imagine a horizontal plane passed through the eyes, at right angles to the plane in which the subject is being turned. This horizontal plane passed through the eyes will vary in position with the position of the head. The position of this horizontal plane always indicates the form of the nystagmus.

The nystagmus is always opposite to the direction of the turning. If the head is erect, the nystagmus is horizontal; if the head is bent toward the shoulder at an angle of 45°, the nystagmus is oblique and upward. If the head is bent fully toward the shoulder to form an angle with the vertical of 90°, the nystagmus is vertical. If the head is bent directly forward so that the face looks downward and the turning is to the right, the nystagmus will be rotary and to the left. If the head is bent backward so that the eyes look upward and the turning is again to the right, there is rotary nystagmus to the left. The concavity of the nystagmic curve is upward, i. e., opposite to the position of the head. In the preceding case the concavity of the nystagmic curve looked downward.

VERTIGO AND DISTURBANCES OF EQUILIBRIUM.

Baranay's studies have led him to formulate the following laws governing spontaneous vertigo and nystagmus:

(1) Vestibular nystagmus is always influenced by the position of the head.

(2) A person exhibiting vestibular nystagmus tends to rotate within the plane of the nystagmus and in the direction opposite to that of the quick nystagmic movement.

This tendency to rotation is about an axis passing through the patient's head. If a person is seated with head erect and is turned ten times to the right and the rotation is suddenly stopped he exhibits a marked nystagmus to the left. He also experiences vertigo. If the patient stands, the nystagmus being in the horizontal plane, the reaction movement will be, not falling, but a gradual turning in the horizontal plane to the right. If the patient bends the head forward or downward at an angle of 90°, the plane of the nystagmus becomes vertical. The

nystagmus is to the left and the head tends to turn to the right shoulder. If the head is bent directly backward at an angle of 90° and the turning is to the right, the nystagmus is to the left and the patient tends to fall to the right.

In the caloric tests, or in the nystagmus following acute labyrinthitis, the nystagmus is rotary and the plane vertical rather than horizontal. The patient falls in the direction opposite the quick movement. In the suppurative labyrinthitis the nystagmus is almost always toward the sound ear, so that the patient falls in the direction of the diseased ear. It must not be forgotten, however, that in certain forms of circumscribed irritative labyrinthitis the nystagmus is in the direction of the diseased ear, so that the patient tends to fall in the direction of the sound ear.

Baranay holds that disturbance of equilibrium is characteristic only of the acute stage of labyrinthine disease and that it regularly disappears as the lesion advances either toward resolution or toward destruction of the vestibular structures. This view is supported by the fact that vestibular ataxia as a subjective symptom rapidly disappears after surgical destruction of the labyrinth. Baranay, therefore, attaches little importance to disturbed equilibrium as a diagnostic sign in the latent or the chronic stage of suppurative labyrinthitis. He believes that in the chronic stage of suppurative labyrinthitis, the vestibule, in the great majority of cases, is no longer responsive to the usual stimuli; in other words, that its function is abolished and it is illogical to expect a disturbance of equilibrium from an organ which is no longer susceptible to stimulation.

Von Stein, apparently, believes that at no stage of suppurative labyrinthitis are disturbances of equilibrium absent, and that while these disturbances may not interfere with the patient's ability to walk or stand normally, they may be clearly demonstrated by requiring him to perform certain acts in which he is not practiced by daily custom, i. e., jumping or hopping with the eyes closed.

It is now generally conceded that vestibular ataxia is a symptom induced by vestibular irritation acting upon the diseased labyrinth or by ablation of its function through disturbed balance of the unopposed healthy organ. Further, the ataxia disappears as a subjective symptom after the diseased labyrinth has been destroyed surgically or its function completely annulled. If, therefore, the tests of Von Stein elicit a true vestibular ataxia in the chronic stage of labyrinthine suppuration, the ataxia is due, not to irritation of the diseased labyrinth and non-functioning labyrinth, but to excitation of the sound labyrinth which is no longer balanced by an unopposed healthy organ. (Kerrison.)

NYSTAGMUS IN HYSTERIA.

In dealing with hysterical patients who have an intercurrent aural disease, many contradictions of the regular tests may appear. Many neurasthenic patients under certain conditions exhibit uncontrollable eye movements which are not of vestibular origin and in no way resemble vestibular nystagmus. It is obvious that vertigo and apparent disturbance of equilibrium may in neurasthenic patients depend wholly on functional disorders of the general nervous system.

VERTIGO.

Vertigo which is not accompanied by nystagmus even when the eyes are turned strongly in the direction away from the suspected labyrinthine lesion, and which is not influenced by the position of the eyes, has little value as pointing to labyrinthine disease. Disturbances of equilibrium which are not influenced by the position of the head can hardly be assumed to be of vestibular origin.

What use can these tests be put to clinically? In a normal individual, as each labyrinth sends an equal stimulus to the eyes, no movement results, the eyes being in equilibrium. If, however, one labyrinth is irritated, this labyrinth sends a greater stimulus to the eyes, upsets the normal equilibrium and pulls the eyes toward its own side. If the irritation of the labyrinth caused by disease continues to a suppurative involvement of the labyrinth, and its destruction, the attacked labyrinth loses all power of function. In this case the well labyrinth alone sends impulse to the eyes. The living labyrinth in this case controls the situation and pulls the eyes in its direction. The turning test and the caloric test give the physician power to stimulate the other labyrinth at will. The reactions of the normal labyrinth to these tests have been accurately proven. If, in a case of suspected disease of the labyrinth, these tests are applied and the normal reactions are not given, the inference is drawn that the labyrinth is diseased. The easier of the two tests to apply is the caloric test. If a labyrinth is partially destroyed, the responses to the caloric test are weak compared with those given by the normal labyrinth. If, however, the labyrinth is completely destroyed, the diseased labyrinth gives no response whatever to the caloric tests. In this way the caloric tests can be used as a measure of the intactness of any given labyrinth. The turning tests should confirm the caloric tests.

VESTIBULAR SYMPTOMS IN ACUTE SUPPURATIVE LABYRINTHITIS.

Kerrison groups the symptoms of vestibular irritation in an imaginary case as follows: Suppose that a patient has an acute otitis media on the right, and that the infection has spread to the inner ear or labyrinth. Shortly after the invasion of the labyrinth the patient has distressing vertigo which forces him to go to bed. The eyes show a marked rotary nystagmus to the left or the sound side. The nystagmus is present in whatever position the eyes may be placed, but it is increased when the eyes are turned to the sound side, that is, in the direction

of the quick nystagmic movement, and is diminished when the eyes are turned in the opposite direction. The vertigo is rotary. If the patient is supported in a vertical position, objects seem to rotate in a vertical plane, usually from the right, the diseased side, to the left, the sound side. If the patient lies on his back, the plane of seeming rotation is changed from the vertical to the horizontal. If able to stand, he stands unsteadily and tends to fall toward the right or the diseased side. At the onset, the patient usually has nausea and vomiting. All these symptoms are lessened in severity while the patient lies in bed. The patient, therefore, prefers to be in bed, and lies on the diseased side, with the face towards the pillow and the eyes turned in the opposite direction. This position is assumed because it gives the greatest comfort.

COURSE OF THE DISEASE.

All of the above symptoms subside, as a rule, fairly rapidly and in a somewhat regular order. That is, the vertigo and the ataxia regularly disappear before the nystagmus. By the end of the first week the vertigo may have disappeared, but the nystagmus is still present. Sudden head movements may bring back all the symptoms. From the end of the second to the end of the fourth weeks, not only the vertigo and the ataxia, but the nystagmus, have completely disappeared and the patient is able to move or walk without disturbance.

During the course of the acute circumscribed inflammation of the labyrinth just described, if the left ear was normal, the persistance of function in the diseased labyrinth can be easily demonstrated. Warm water injected into the canal increases the nystagmus, and cold diminishes it, or may even cause it to disappear. Suppose, however, the disease goes on to total destruction of the right labyrinth, or suppose that the labyrinth has been destroyed by operation. With the labyrinth destroyed by either method, neither heat or cold produce any effect.

NYSTAGMUS IN CEREBELLAR DISEASE.

Disease of the cerebellum, as well as disease of the vestibule, can cause nystagmus. As disease of the cerebellum is often caused by disease of the labyrinth, the two factors occasionally act on the eyes at the same time. Cerebellar abscess is most often associated with labyrinthine suppuration of a diffuse or general character, not with circumscribed labyrinthine disease.

Nystagmus in cerebellar abscess may be toward the sound side or the diseased side. More often it is toward the diseased side. Cerebellar abscess is usually found in connection with labyrinthine suppuration, so that both factors, the labyrinth and the cerebellum, play a part in producing the nystagmus. The following possibilities must be differentiated:

(1) With nystagmus toward the diseased side there may be (*a*) a circumscribed labyrinthine suppuration; (*b*) a cerebellar abscess.

With a circumscribed suppuration, the labyrinth would still be excitable and would react to heat or cold. There would also be signs of a labyrinthine fistula, that is, aspiration and compression of the air in the external auditory canal would cause movements of the eyes. If, however, the reaction to heat and cold was lost there might still be reaction to pressure or to galvanic stimulation. In this case the diagnosis could not be made from the nystagmus. In such a case, with nystagmus to the diseased side and reaction to pressure and to galvanism, but not to heat or cold, the labyrinth operation is indicated after the radical. After the removal of the labyrinth, if the nystagmus which was formerly directed toward the diseased side should then be directed to the sound side, the diagnosis of labyrinthine suppuration without involvement of the cerebellum could be made. If, however, after operation on the labyrinth, the nystagmus was still directed toward the diseased side, and does not change to the sound side, the nystagmus must come from some intracranial origin, for a sound vestibule, if the opposite vestibule is destroyed, causes nystagmus to its own side.

(2) Suppose there is a nystagmus to the diseased side and the vestibule is shown by tests not to be functioning.

In this case the nystagmus must be intra cranial, and this intracranial stimulation must be greater than the stimulation from the opposite and intact vestibule. The nystagmus to the diseased side could point only to an abscess in the cerebellum. In such a case, due attention would, of course, be paid to the pulse, the temperature and the other general signs of cerebellar involvement.

There exists a third possible combination of nystagmus in cases of suspected cerebellar abscess.

(3) The nystagmus is directed, not toward the diseased side, but toward the sound side, and the labyrinth is not excitable.

In this case the nystagmus could come either from the vestibule or from the cerebellum, and diagnosis from the nystagmus could not be made. In this case the cerebellar suppuration has proceeded so far that all function of the cerebellum is lost. In such a case, if only the labyrinth is diseased, after operation the nystagmus is extreme and directed to the sound side. It, however, gradually disappears. Should there be a cerebellar abscess, however, associated with the labyrinthine suppuration, the nystagmus after operation does not decrease; it increases instead and it is reversed and directed toward the diseased side. From these signs the intracranial origin of the nystagmus, that is, cerebellar involvement, can be diagnosed for a certainty.

(*To be continued.*)

AN epidemic of measles is reported in Pretoria. Up to the present, the inhabitants of three hundred houses have been infected, and in all about one thousand cases have been reported. The schools are being closely watched, but the health officials believe that the epidemic is sufficiently under control to obviate the necessity of closing them. — *Jour. Am. Med. Asso.*

Reports of Societies.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

THIRTY-FOURTH ANNUAL MEETING, HELD AT THE ARLINGTON HOTEL, WASHINGTON, D. C., MAY 3, 4 AND 5, 1910.

FIRST DAY, TUESDAY, MAY 3.

THE President, DR. WILLIAM ALLEN PUSEY, of Chicago, in the chair.

PRESIDENT'S ADDRESS — THE THERAPEUTIC USE OF REFRIGERATION, PARTICULARLY WITH SOLID CARBON DIOXIDE.

DR. PUSEY said the method of using solidified carbon dioxide for therapeutic purposes had been before the profession for three years. It had, he believed, had a wide trial, and it now had a very respectable literature, so that one could form an approximate estimation of its field of usefulness and its limitations. He, therefore, availed himself of this opportunity to undertake to review the method and its results in the light of the experience of others as well as himself. Solid carbon dioxide was suggested as a substitute for liquid air as an available substance of excessively low temperature which could be used to meet the same therapeutic indications as were met by liquid air. The principle underlying the therapeutic use of solid carbon dioxide, as of liquid air, was the production of a relatively deep, sharply defined inflammatory reaction in living tissue by sudden intense freezing. The first advantage of the method was that the reaction could be regulated so that one could accurately produce all degrees of effect upon tissues, from an evanescent inflammatory reaction to a reaction so intense that it resulted in complete destruction of the involved tissues. The depth of freezing from solid carbon dioxide was controlled by the degree of pressure made in the application and the duration of the application of the snow, and the freezing which resulted therefrom was the most important factor in the effect upon tissues. The therapeutic indications for the use of refrigeration were found in the following conditions: First, those in which production of a stimulating reaction was beneficial. Here only conditions covering relatively small areas would come into consideration because of the impracticability of using the applications over very large surfaces. Second, those in which it was desired to destroy certain tissues in the skin by the production of an interstitial sclerosis. Third, those in which it was desired to produce immediate destruction of masses of diseased tissue in the skin. It was the second one of these indications which gave this method its chief claim to therapeutic usefulness, for it furnished a practical means of destroying the connective tissue stroma around them, and thus furnished a method of destroying certain tissues selectively and replacing them by an interstitial scar tissue formation which showed little or no scarring on the surfaces. The various dermatoses in which, upon the basis of these indications, the method might have a field of usefulness, occurred, of course, to all, and in many of them it had been tried.

Foerster, Heidingsfeld, Winfield and others had gotten excellent results by this method in the treatment of senile keratoses. The same was true in the treatment of superficial epitheliomata. Personally, Dr. Pusey said, he did not believe that carbon dioxide was the method of choice in epithelioma, excepting for very small and superficial lesions. In larger or deeper seated lesions he preferred the x-rays. In conclusion, he expressed the belief that refrigeration with liquid air or solid carbon dioxide was a method of treatment that was an advance of value in the treatment of a considerable group of lesions of the skin, some of which had been intractable to other methods at our command; and, second, that the introduction of the solid carbon dioxide had made the method practically available.

EXTRAMAMMARY PAGET'S DISEASE, WITH REPORT OF A CASE OCCURRING ON THE FOREARM, ASSOCIATED WITH A NAEVO-CARCINOMA.

DR. M. B. HARTZELL, of Philadelphia, read this paper, which he illustrated with microphotographs, and which included the report of a case, with its clinical and histological features. He compared this with other cases which resembled it more or less, and discussed the relationship of the dermatitis to Paget's disease and carcinoma. He said it seemed to him that the cases which he had ventured to call extramammary Paget's disease afforded special opportunity for determining the real nature of this extremely interesting malady — for deciding whether the disease was one *sui generis*, as maintained by Unna and others, or whether it was carcinoma from the beginning, as was asserted by a number of recent writers. The careful study of these cases ought also to enable us to determine whether the cutaneous disease was a primary one, followed only after a considerable interval by carcinoma, as had long been believed, or whether, as Jacobaeus, Hirschel and others asserted, the skin symptoms were only a secondary manifestation of a deeper lying carcinoma which had already existed for some time. The correct decision of this question was of the utmost practical importance, for upon it depended the plan of treatment to be adopted. If the former view was the correct one, then there was a reasonable prospect that early and prolonged treatment by the x-ray or by radium might effect a radical cure; but if the latter, then every day's delay in thoroughly removing by surgical measures the entire disease was valuable time lost, and impaired by so much the patient's chances of recovery.

DR. MARTIN F. ENGMAN, of St. Louis, said there was no more fertile field, nor one that offered better prospects in the study of cancer, than did this subject of malignant papillary dermatitis.

DR. JAMES M. WINFIELD, of Brooklyn, said that two or three years ago he saw a woman with a peculiar, raw-looking patch over the region of the scapula, just where the tip of the corset steel irritated the skin. She stated that she had first noticed it about eight years ago, when she consulted a dermatologist, and he told her that it was a seborrheal eczema. It failed to heal, however, and when Dr. Winfield saw her the lesion was typical of Paget's disease of the nipple. It was excised, and at the same time a large, congenital pigmented mole over the breast was also removed. Pathologically, the patch over the scapula gave the typical picture of Paget's disease, and the mole showed the same histological features.

DR. HARTZELL, in closing the discussion, said that not long ago he had been inclined to agree with Unna that Paget's disease was a disease *sui generis*, but he was now pretty well convinced that it was carcinoma from the beginning — a carcinomatous dermatitis. It was essential, he thought, to enlarge our view as to what carcinoma was. There were changes in the epithelium which preceded for a considerable time the proliferation of the epidermis, and these changes we must regard as carcinomatous, just as we regarded as carcinomatous the overgrowth of the epithelial cells themselves.

SYRINGOCYSTOMA.

DR. OLIVER S. ORMSBY, of Chicago, read this paper, in which he recorded the findings revealed in the study of a case in which the clinical diagnosis of syringocystoma was made. He said that in the mass of literature on this subject there appeared to be pretty distinct groups of cases which presented a sufficient number of common details, both clinical and pathological, to explain why all had been classed together by most writers. In Group 1 to which the cases of multiple benign epithelioma belonged, the disease appeared to be hereditary. The lesions began early in life, and often several members of one family were affected. Here, the lesions predominated on the face and head, and were variously described as nodules of different sizes, whitish, yellowish-red, translucent, etc., in some instances going on to softening and to evolution — true epitheliomata. Brooke, Fordyce, Hartzell and others had traced the origin of these epithelial growths to the rete and the sheaths of the hair follicles. To identify the second group, various terms had been used, according to the conception of the writer as to the point of origin of the affection. Among these terms were eruptive hydradenoma, adenoid epithelioma of the sweat glands, syringocystoma, lymphangioma, etc. In the majority of these cases the lesions occurred most often on the trunk. Heredity played no part in this affection. The lesions varied in color, size and shape, but they were nodules and perhaps much softer in consistency than those described in the first group. In the latter, the sweat glands, ducts, the lymph and blood vessels had been thought to be the points of origin of the growths. Dr. Ormsby then gave in detail the history of a case in which the clinical diagnosis of syringocystoma was based upon a due consideration of all the points, both clinical and histological. Clinically, it was more extensive than other recorded cases, and spontaneous disappearance of lesions occurred, which had not been recorded previously. It was entirely unlike any case of multiple benign cystic epithelioma. Histologically, the sections showed the most marked pathological process at all times in the region of the sweat ducts. Some sections apparently demonstrated the fact that the cells were the proliferation product of the cells of these ducts. A connection between the hair follicle or the epidermis and the cell masses could not be demonstrated. Whether the sweat glands themselves added to the growth was not proven, although it seemed probable. Finally, from the fact that the lesions developed over so great an area, practically symmetrical, and showed such marked effects on the involvement of the sweat apparatus, the problem of local irritation from some error of metabolism or otherwise must be ruled out, but so far that work in this respect had been neglected.

DR. JAMES NEVINS HYDE, of Chicago, said the case described in Dr. Ormsby's paper was on the whole one of the most extraordinary he had ever seen, and when he first saw it, it did not impress him as a case of syringocystoma. He could corroborate what had been said as to the disappearance of some of the lesions.

DR. J. A. FORDYCE, of New York, said that Dr. Ormsby's paper cleared up the confusion that had existed in his mind, and doubtless in the minds of others, regarding the identity or non-identity of syringocystoma and multiple benign epithelioma. This confusion was due to the close clinical similarity of the two types, and to the fact that the first observers of the affection confused the nomenclature. There was, however, a clear distinction between the two. One had its origin in the sweat glands; the other in the basal layer of the epidermis or the hair follicles.

DR. CHARLES J. WHITE, of Boston, said he did not think that multiple benign cystic epithelioma was a very rare disease. He had had three or four examples under his own observation, and had become convinced that the lesions could have their origin from various sources, the hair follicles, epidermis, sweat glands or ducts, etc. In syringocystoma he had examined many sections, and he regarded the sweat apparatus as the point of origin of the lesions.

DR. WILLIAM A. PUSEY, of Chicago, said he had examined Dr. Ormsby's serial sections, and there was a sharply circumscribed cell infiltration in distinct relationship to the sweat glands. This looked very much as though it were due to some irritant excreted by the sweat glands, which was producing an inflammatory process around the glands and proliferation of the epithelioma of the glands.

FURTHER OBSERVATIONS ON THE TECHNIC OF AN EFFICIENT PROCEDURE FOR THE REMOVAL AND CURE OF SUPERFICIAL MALIGNANT GROWTHS.

DR. SAMUEL SHERWELL, of Brooklyn: His method of dealing with superficial malignant growths consisted, first, in curettage, which should be thorough, deep and efficient. Immediately following this there should be an equally thorough application of an escharotic, preferably, in the writer's opinion, a 60% solution of the acid nitrate of mercury (Squibb), which should be allowed to remain, with various reapplications at the time of operation, for varying lengths of time, according to the delicacy or density of the tissues involved. From five to twenty minutes would be about the limits. The final step in the operation was the at least superficial neutralization of the caustic agent by some alkaline medium, and of these, sodium bicarbonate seemed to be the best. A few grains of this, powdered on and pressed into the wound, immediately formed a plain scab or crust which should be allowed to remain *in situ*, untouched and dry, until it fell or rather was pushed off by and with the process of healthy repair beneath, leaving a healthy scar, and usually a relatively insignificant or not very noticeable one. Dr. Sherwell said his experience with this method, which had never changed, had been coincident and identical, or almost so, with that of his dermatological life and practice, a period of nearly forty years. During that time he had operated on many hundreds of these cases of malignant growths in this manner. Recurrences or relapses had been comparatively few; he could not give the exact figures, but it was probably less than 10%, and usually a second operation would diminish even that. The author claimed, for his special technic, rapidity of results, decided freedom from recurrences, relative absence of cosmetic deformity, and, when the procedure was thoroughly carried out, little or no pain, either during or after the operation, and no necessity for repeated dressings when the indications were properly cared for. In connection with his paper, Dr. Sherwell exhibited a number of photographs, showing the lesions before and after treatment.

DR. J. A. FORDYCE, of New York, said he could personally testify to the efficiency of the acid nitrate of mercury, as advised by Dr. Sherwell, in the treatment of superficial epitheliomata. The speaker said he had used it in a number of cases with excellent results.

DR. HENRY W. STELWAGON, of Philadelphia, said that for the past four or five years he had preferably treated superficial epitheliomata by thorough curettage, followed by the application of some caustic, and among the latter, he thought the acid nitrate of mercury solution was one of the best, as the wound, if small, required no subsequent dressing; a crust was formed under which healing went on, leaving a practically healthy scar at the end of three or four weeks.

Dr. Edward B. Bronson, of New York, said it was especially in cases where the orbit was involved that the most remarkable results had been obtained by Dr. Sherwell.

Dr. Sherwell, in closing, said he had resorted to this method for thirty-five years, and his faith in the remedy had become stronger as time went on. Curiously enough, the most unfavorable cases, in his experience, had been those in which the lesion was situated about the center of the cheek; whether that was due to the peculiar circulation of these parts, or to the adhesions of the skin to the deeper tissues, he did not know; in fact, it was difficult to frame a reason.

CANCER IN TAR WORKERS.

Dr. Jay Frank Schamberg, of Philadelphia, in this paper, stated that cancer of the skin exhibiting special characteristics had been encountered in chimney-sweeps, and in tar and paraffin-workers. He reported in detail a case of multiple cancer of the skin in a tar-worker who developed several scores of epitheliomatous lesions in various stages of development upon the hands and forearms, and a large epithelioma upon the scrotum. That something resident in coal tar, crude paraffin and soot was capable, after the lapse of years, of stimulating the growth of epithelial cells, and of leading to cancer in certain subjects, seemed indisputable. Ludwig and others had suspected carbolic acid, which he likewise found in tobacco residue, but there did not seem to be much support for such an assumption. Inasmuch as radium had proven to be capable of stimulating epithelial proliferation, and cancer could be produced by the x-rays, the thought occurred to Dr. Schamberg to determine whether coal tar emitted any rays. To test this, he placed a copper cent, a flat key and a small brass numeral upon a photographic plate in a pasteboard negative box lined with black paper. Upon the under surface of the lid he attached a piece of cardboard smeared with coal tar, so that the tar faced downwards. This box was inclosed in a black japanned tin cash box, and the latter was shut in a dark closet for twenty-four hours. When the plate was developed, a distinct shadowgraph of the three objects was seen upon the negative. This work was done so recently that there had not been time to carry out further investigations. If coal tar was proven to be radio-active, it would seem that this radio-activity might be responsible for the cancer in tar workers. Volkmann and other writers long ago noted that uncleanliness, i. e., negligence in removing tar or paraffin from the skin, was a factor in the production of the cancer. Tar might be lodged in the orifices of the skin, or in the furrows of the scrotum, and exert for years an influence upon the adjacent epithelial cells. Furthermore, only certain kinds of coal seemed to be provocative of the cutaneous changes. In Germany, the so-called brown or cannel coal from which paraffin was made was responsible. Chimney-sweep cancer appeared to result almost exclusively from the burning of "pit coal" used for fuel in England. It was possible that certain coal might contain radio-active substances and that in other coal such substances might be absent.

Dr. Grover W. Wende, of Buffalo, referred to a case of keratosis follicularis resulting in multiple epithelioma in which there was no evidence of external irritation. He believed that cases like those reported by Dr. Schamberg, and his own, offered something toward an explanation of the cause of the disease, and emphasized the importance of reporting them in full.

Dr. M. B. Hartzell, of Philadelphia, in connection with the statement made by Dr. Schamberg that he had found coal tar to be radio-active, said we should not lose sight of the fact that physicists had found that many substances were more or less radio-active. Every sort of substance, almost, had been found to affect a photographic plate.

Dr. J. A. Fordyce, of New York, said that observations regarding the etiology of cancer along the lines studied in Dr. Schamberg's paper were very interesting and seemed to negative somewhat the parasitic theory of the disease. They pointed rather to the abolition of one function of the cell, and the exaggeration of its reproductive function, as suggested by Oertel.

Dr. James Nevins Hyde, of Chicago, referring to cancer of the scrotum, said that the boy chimney sweep of the last century was brushed up and down the chimney, his scrotum coming in contact with the soot, which produced the cancer.

NODULAR TUBERCULOSIS OF THE HYPODERM.

Dr. Grover W. Wende, of Buffalo: This was the clinical report of a case in which deep-seated nodules constituted the only type of lesion. They were limited to the face and disappeared without apparent alteration of the skin, but produced upon disappearance of ankylosis of the temporo-maxillary articulation and deafness of the right ear. The duration of the eruption was six years. By microscopic study, tuberculin tests and guinea pig inoculations, the case was proven to be one of nodular tuberculosis of the hypoderm. It was a form of tuberculosis of the skin which showed no analogy with the generally recognized forms of cutaneous tuberculosis due to the invasion of the integument by the tubercle bacilli, like that of lupus vulgaris, tuberculosis verrucosa, tuberculosis disseminata and tuberculosis ulcerosa.

Dr. Howard Fox, of New York, mentioned a similar case that he had shown at a recent meeting of the New York Dermatological Society, in which a probable diagnosis of Darier's type of sarcoid was made.

Dr. A. Ravogli, of Cincinnati, said he would not be surprised to learn that the case reported by Dr. Wende began in the form of an erythema induratum from the skin, or from a tubercular ulcer fron the mucous membrane of the mouth, from which the tubercular process found its way to the joint.

Dr. J. A. Fordyce, of New York, said the case so well reported by Dr. Wende was an illustration of the value of careful clinical observation combined with histological investigation. With the aid of the latter we were broadening our clinical ideas in regard to tuberculosis of the skin.

Dr. William T. Corlett, of Cleveland, said that observation taught us that many clinical forms of superficial tuberculosis of the skin existed.

Dr. Wende, in closing, said he believed that in the case he had reported the disease primarily occurred locally in the skin. The case illustrated the importance of biopsy for microscopical examination as there was no suspicion of the real condition before it was made.

REPORT OF A CASE OF SPOROTRICHOSIS IN MAN.

Dr. James Nevins Hyde and Dr. J. D. Davis, of Chicago, presented a paper on sporortrichosis occurring in a patient who lived in North Dakota, and who had been in contact with horses that were supposed to have suffered from glanders. It was discovered that these horses were probably the victims of mycotic lymphangitis (pseudo-farcy), and the authors reported that the Bureau of Animal Industry in Washington recognized the identity between the organism obtained from animals in North Dakota similarly affected and those presenting similar symptoms two years ago which had been studied in Butler, Pa. Further, the Pennsylvania organism had been recognized as identical with the Chicago organism by Drs. Frothingham and Page, of

Harvard University; and, finally, the two authors recognized the identity between the organism obtained from the human patient in North Dakota and specimens of the Butler organism sent to Chicago. The paper concluded with a demonstration of the essential differences between the sporotrichum Schenckii and the saccharomyces farciminosus of Tokishige.

DR. CALVIN S. PAGE, of Boston, said the paper of Drs. Hyde and Davis was of interest not only from a veterinary point of view, but from the standpoint of human beings, as this disease had been mistaken for both syphilis and tuberculosis. The affection had been traced to a species of mold growing out-of-doors which infected the horses. It had also been found in the common rat, which was the most satisfactory animal for experimental inoculation. For culture purposes, potato was very satisfactory. The pus from one of these lesions should be freely smeared over the cut potato, and the culture would begin to grow in a few days at the ordinary room temperature.

DR. JOHN REICHEL, of Philadelphia, said that early in 1907 the attention of the state veterinarian of Pennsylvania, the late Dr. Leonard Pearson, was called to several cases of suspected glanders in and about Butler County, Pennsylvania. After a careful study of these cases, the clinical diagnosis of epizoötic lymphangitis was made by him, and the diagnosis was later confirmed in the laboratory and an organism was isolated which was recognized as the sacchromyces farciminous.

DR. H. W. STELWAGON, of Philadelphia, said that cases of sporotrichosis in man, perhaps limited to one or two cold abscess-like formations, were probably not as uncommon as had been hitherto believed, as cases heretofore looked upon as syphilitic gummata, because they cleared up under the use of potassium iodide, might possibly have been examples of this disease.

The discussion was continued by DR. WILLIAM A. PUSEY, of Chicago, and was then closed by DR. HYDE.

(To be continued.)

Book Reviews.

Congenital Dislocation of the Hip. By H. J. JACKSON CLARKE. London: Baillière, Tindale & Cox. New York: Paul B. Hoeber.

This is a clearly printed and well-illustrated monograph giving the writer's experience with cases of congenital dislocation of the hip treated according to the manipulative method advocated Professor Lorenz, and two by a method of open incision and stitching the capsule described by the writer in 1909.

The results in 30 cases are as follows: 30 cases (39 dislocations), 18 double, 21 simple; 18 double, 12 cured, 6 failures (2 of them being anteverted but stable); 21 simple, 17 cured. Of failures, 2 have been later treated by open incision; 1 is cured and the result in the other is still uncertain, the case being under treatment.

While these results are excellent, they are not unparalleled, and the book adds but little to the existing knowledge of the subject; it is, however, to be recommended as a clear and frank statement of a painstaking and sensible surgeon who has carefully noted his experiences with 40 cases.

Preventable Diseases. By WOODSHUTCHINSON, A.M., M.D. Boston and New York: Houghton, Mifflin Company. 1909.

The Conquest of Consumption. By WOODS HUTCHINSON, A.M., M.D. Boston and New York: Houghton, Mifflin Company. 1910.

These two volumes by Dr. Hutchinson deserve more than passing comment, for they not only present the sort of knowledge that every one ought to have about disease, but present it in a form and manner that are original and illuminating to physicians as well as to the general public.

In his introductory chapters on "The Body Politic" and "Our Legacy of Health," Dr. Hutchinson gives an admirable biologic description of the nature, origin and evolution of the human organism, in terms whose literary facility and vividness of illustration, allusion and analogy make his exposition at once attractive and convincing. In successive chapters he similarly treats of the common diseases to which flesh is heir, explaining the etiology, pathology, treatment and prophylaxis of each, always with variety and flexibility of style, always with a buoyant and contagious optimism. The story of tuberculosis is told in singularly dramatic and inspiring fashion, yet without ever becoming theatrical. Particularly encouraging is Dr. Hutchinson's attitude towards disease, "as a lever to raise to a higher plane the health, vigor and happiness of the entire community," a serviceable agent in the evolution and victorious irresistible progress of man, whom he picturesquely describes as "the toughest, most resourceful, most ferocious and dangerous animal that walks the face of the earth." Civilization to him is not a curse, but the best cure for its own evils as well as those of savagery. In short, he is an idealist in medicine, yet never a visionary, for his ideals are always sane and rational and wholesome, and he tells about them like a good physician talking hopefully to an intelligent patient. It is true that occasionally his facility of phrase leads him into such questionable sensationalism as calling a shrewd country practitioner a "keen-eyed old sleuth-hound of the fever trails"; and in the chapter on surgical sepsis, he betrays his medical bias by portraying an aseptic technic that would be an intolerable scourge and torture to the flesh of surgeon and patient alike. But such verbal and technical errors may well be pardoned for the sake of the never-failing vividness and variety of diction and composition which stimulate attention and carry conviction to the end.

"The Conquest of Consumption" is an expansion of the chapters on tuberculosis in "Preventable Diseases," written in the same temper, with the addition of much new and effective material.

In these two books, then, Dr. Hutchinson has done a valuable work, and has shown himself at once a man of science and a man of letters. The vitality, vigor and versatility of his epigrammatic style make it an excellent vehicle for his sound and original ideas. His books should be widely read by physicians as well as by the laity, for they tell the truth and tell it in new and compelling form.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 15, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE QUESTION OF PASTEURIZED MILK.

THE New York Milk Committee of the Association for Improving the Condition of the Poor, having expressed its great regret at the announced discontinuance of the Straus depots, and since then having received many requests for definite information as to the attitude of the committee in regard to pasteurized milk, has issued, through its secretary, Wilbur C. Phillips, a public statement on the matter. In this the questions put are grouped into three classes:

1. Why, if the committee does not know if pasteurized milk is as nutritious as raw milk, does it advocate its being dispensed in the Straus depots? Answer: The attitude of the committee on this matter is one of neutrality. It believes that facts are as yet lacking to demonstrate conclusively that there is any great difference in the nutritional value of milk, raw or pasteurized, postponing an opinion on this point until it has been definitely determined by thorough scientific experiment. But, while the committee recognizes that it is as yet an open question, it also recognizes, with many sanitarians and public health authorities, that, quite apart from any chemical change which may or may not be effected by subjecting milk to heat, the killing of pathogenic germs by the process known as pasteurization is a protection against infection and contagion. The committee, therefore, approves of the pasteurization of all milk which has not been produced under sanitary conditions and which cannot be supplied to the consumer with sufficent low bacterial content to offer safety from milk-borne infection. It believes that the ideal milk for infants, as well as adults, is a certified or guaranteed milk drawn from cows free from tuberculosis and kept under conditions which satisfy every sanitary requirement and which offer complete protection against infection and contagion. It believes in encouraging by all possible means the production and consumption of a clean raw milk, which does not need the protection afforded by pasteurization, but it also recognizes the difficulties in securing milk of this character immediately; and it therefore approves of the pasteurization of all other milk.

2. Why does not the committee wait before advocating the use of pasteurized milk until it completes its investigation on the comparative nutritive value of raw and pasteurized milk? As a neutral party, the committee can respect the opinion of those who believe that pasteurization does not affect the nutritional value quite as much as that of those who hold that it does. This is simply a question of nutrition — in New York City a question principally of the growth of children. But in New York the main problem appears to be, not, How we shall secure the best growth for our children, but, How can we best keep them alive so that they can grow at all? In this life-and-death matter the main thing, then, is not, How is the milk treated, but, Is the milk clean and safe?

3. Why, if the committee commends the work of the Straus depots, which dispense pasteurized milk, does it not use pasteurized instead of raw milk in its own depots? The milk which the New York Milk Committee uses comes from cows free from tuberculosis, kept under conditions which satisfy every sanitary requirement; hence it is felt that the protection of pasteurization is not required. On those occasions when it has been necessary to use a milk of inferior quality, pasteurization has been resorted to.

In conclusion, Mr. Phillips goes on to say that because of the disquieting controversy which has arisen regarding the relative nutritional value of raw and pasteurized milk, it is highly important that this point should be settled. This the committee believes can be done only by a scientific investigation in the laboratory and upon infants themselves, and such an investigation, to determine the matter, is now to be undertaken by the committee. This, he thinks, ought not to consume more than six or eight months, and ought not to cost more than $3,000 — at the most $5,000. In carrying on this work the committee has been offered exceptional facilities. Dr. H. S. Sherman, professor of nutrition, Columbia Uni-

versity, has placed at the disposal the fine equipment of that institution for some of the nutritional studies. Dr. Godfrey R. Pisek, professor of children's diseases at the Post-Graduate Medical School, and physician in charge of the committee's infant depots, will supervise the infant studies, with the assistance of leading physicians who have volunteered their help. The laboratories of Dr. Charles E. North, chairman of the committee's section on sanitation, bacteriology and public health, have been offered for the chemical and bacteriological work. Dr. Milton J. Rosenau, professor of preventive medicine and hygiene in Harvard Medical School, has promised his hearty co-operation in the investigation. Dr. Rosenau, in behalf of the Boston Committee on Milk and Baby Hygiene, is shortly to begin a three years' study of milk in its various aspects, and it has been agreed between him and the New York Milk Committee that the work along this special line carried on in Boston is to be utilized to supplement that of the New York committee, thus assuring, in a co-operative way, the final solution of this perplexing question.

ASIATIC CHOLERA.

FROM India, which has for ages been the home of cholera, this disease has been invading Europe and the West by two main routes. The first of these is by way of Mecca, which may be considered a subsidiary station. The fatalistic Mohammedan makes his pilgrimage to the Prophet's shrine from the East, and carries with him thence the cholera; his fellow-worshipers from Africa and Europe proceed eastward, and on returning to their homes distribute it throughout Mediterranean regions. The second route is by way of the Caucasus, the Don, the Dneiper and other rivers coursing northward into Russia, and finally to St. Petersburg and the Baltic. It is the second of these two routes which now concerns, though not gravely, the western world.

From mediaeval Russia the present epidemic of cholera has reached Berlin and has spread to Austria and Italy. Our coast quarantine authorities are well known to be cautious, experienced and altogether able to cope with any possible attack. Nobody among our people really need fear a cholera epidemic, especially since the incubation period is from one to five days, wherefore in any possible case among passengers from Europe the invasion must have developed before reaching our ports. To this consideration, however, one exception must be recognized: That is, the possibility of infection by "cholera carriers," who, like typhoid carriers, may not themselves have had the disease, though potential transmitters of it to others.

We have characterized Russia as medieval in her attitude toward such infections as cholera; and surely it is just so to stigmatize a condition of things by which all the rest of civilization has through many years consistently been jeopardized, especially in view of the elementary simplicity of cholera prophylaxis. In these premises *Nature* offers some significant observations.

A great change has indeed taken place in most civilized countries in both the public and also the political and professional attitude toward great epidemic outbreaks. Until the appearance of the great school of sanitary reformers represented by Chadwick and Simon, panic and despair were the predominant emotions aroused in the presence of plague, cholera and the like. With a knowledge of what could be achieved by the adoption of efficient sanitary measures these influences, so paralyzing to the mind of the community, have gradually been rendered less effective, especially as the call to preventive and curative work could be made to divert men's minds from brooding and anticipation of evil. It came to be realized how much could be done to ameliorate the sufferings of communities attacked by these diseases, and how successful were measures preventive of transference not only from community to community, but from individual to individual. Much such endeavor, producing such good results, was done even before Pasteur, Koch and Lister.

Such social phenomena were especially marked with relation to cholera. One may at this time see reproduced in various parts of Europe the peculiar phases of the history of the evolution of our methods of dealing with cholera epidemics at different periods. In Russia, and some parts of Italy, where fatalism and apathy prevail, and where sanitary science has not demonstrated its usefulness, cholera still arouses such panic as is naturally followed by the lethargy of despair. In other parts of Europe efforts (oftentimes very inadequate) are making to combat the spread of the disease; whilst in Northern Europe (including such places as Amsterdam and London) the announcement that cholera is imminent simply means a call to renewed sanitary efforts directed by intelligent experience and skill. One of the greatest safeguards of the Americas from Asiatic cholera is Germany's inexorable paternalism in the prophylaxis of disease.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.—For the week ending at noon, Sept. 13, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 21, scarlatina 16, typhoid fever 25, measles 5, smallpox 0, tuberculosis 58.

The death-rate of the reported deaths for the week ending Sept. 13, 1910, was 16.33.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Sept. 10, 1910, was 196, against 196 the corresponding week of last year, making the death-rate for the week 15.24. Of this number 99 were males and 97 were females; 190 were white and 6 colored; 134 were born in the United States, 56 in foreign countries and 6 unknown; 35 were of American parentage, 135 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 28 cases and 3 deaths; scarlatina, 22 cases and 1 death; typhoid fever, 21 cases and 4 deaths; measles, 5 cases and 1 death; tuberculosis, 46 cases and 16 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 14, whooping cough 2, heart disease 16, bronchitis 2. There were 14 deaths from violent causes. The number of children who died under one year was 68; the number under five years, 80. The number of persons who died over sixty years of age was 49. The deaths in public institutions were 87. Anterior poliomyelitis, 2 cases. Cerebrospinal meningitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 1 case and 1 death. Diphtheria, 1 case and 1 death. Scarlet fever, 1 death.

Deducting deaths of non-residents, the total is 171 and the death-rate is then 13.30.

Bequests. — Through the will of the late Miss Caroline M. Martin, of Dover, N. H., public bequests to the amount of $192,000 are made. Among the beneficiaries are a number of hospitals and allied institutions, the more important of which are as follows: Memorial Hospital for Women and Children at Concord, N. H., $5,000; Massachusetts General Hospital, $5,000; Grenfell Hospital, Battle Harbor, Labrador, $2,000.

A Significant Legal Decision. — The Massachusetts Supreme Court has recently handed down a decision of much medical importance. The suit in question was between a property owner and members of the Board of Health of Everett, Mass., the claim being that a mortgagee of real estate is entitled to recover damages from those who have leased the mortgaged premises and used them for a smallpox hospital without the knowledge of the mortgagee as to the use to which the premises were to be put. The ruling of the higher court was that the use of a building as a smallpox hospital entitles a mortgagee to recover the diminution in the value of the property caused by such use.

NEW YORK.

Cost of the Health Department. — The estimate for the cost of running the Health Department for the next year prepared by Commissioner Lederle amounts to $4,076,578, an increase of more than $1,300,000 over the allowance for the department in 1910. The principal increases asked for are the following: Hospitals, $486,056; child hygiene, $320,545; contagious diseases, $113,150; research laboratories, $101,759; milk inspection, $60,510; general sanitary inspection, $57,210.

Use of Antitoxin in Diphtheria. — In the last *Monthly Bulletin* of the State Health Department the attention of the physicians of the state is directed to the advisability of a more prompt and general use of antitoxin in the treatment of diphtheria. The mortality from diphtheria treated by state antitoxin for the last two years was practically 10%, while before the period of antitoxin the mortality in cases of diphtheria was at least 45%. In 1909 there were 2,036 deaths from the disease in the state of New York, which could not have come from less than 20,360 cases, or fully 235 cases of diphtheria for every 100,000 of the population. The following comparative figures as to mortality are then given:

	1902.	1903.	1904.	1905.
State of New York,	37.7	39.02	38.04	28.04
City of New York,	53.0	56.0	57.0	38.0
City of Paris,	20.0	15.0	9.0	6.0

Since 1905, it is stated, there has been no appreciable change in these relative proportions.

	1908.	1909.
State of New York,	28.9	27.05
City of New York,	37.1	38.0

The use of antitoxin being universally acknowledged as incomparably the most prominent factor in reducing the death-rate from diphtheria, it would appear that if the mortality from the

disease in New York state and city exceeds that in Paris, the fault is most likely to be found in the extent or method in which diphtheria antitoxin is employed. Careful investigation of the quality of antitoxin would indicate that Paris has no advantage in this respect over that of the antitoxin supplied by the New York State Health Department. It would seem, then, that the cause of the excessive mortality in the state, at least over that of Paris, is for the most part to be attributed to a failure to utilize antitoxin in the treatment of this disease to anything like the extent which prevails in Paris.

8. Pearce, R. M., and Eisenbrey, A. B. *A Study of Experimental Conditions of Low Blood Pressure of Non-Traumatic Origin.*

2. Lemann's paper on infantilism in hookworm disease consists of the report of one case, with an attempt to classify it. The case, that of a young man of twenty-two, presented the skeletal development of a boy of eleven years, with general, symmetrical retardation of growth, but without mental impairment.

5. Karsner reports four cases of Hodgkin's disease, laying stress chiefly on the pathological findings, and several cases of tuberculous lymphadenitis. He finds a somewhat confusing similarity in the appearance of the lymph nodes from these two classes of cases, but differentiates them by the type of nucleus found in the giant cells in each. In the tuberculous glands, these nuclei possessed relatively solid masses of chromatin, whereas in Hodgkin's disease the chromatin was scanty. He feels justified in saying that Hodgkin's disease is a well-defined pathological entity which produces or is accompanied by a high grade of anemia.

7. After considerable experience with the Wassermann and Noguchi reactions for the detection of syphilis, Kaliski believes that the latter is fully as sensitive in the early stages of syphilis, and more so in the late stages and in metasyphilitic affections. [G. G. S.]

8. Taylor, W. J. *Cystic Disease of the Breast.*

1. Bloodgood presents in a copiously illustrated article an analysis of 89 cases of benign bone cysts and ostitis fibrosa collected from the literature and including his own collection, 18 personally studied cases of giant-cell sarcoma and 3 personally studied cases of bone aneurysm. He divides bone cysts into two groups: those which have a definite relation to ostitis fibrosa and those in the medullary cavity due to other conditions. The first group includes 69 cases as follows: Single cysts with bony shell but no connective tissue lining, 16; cysts with definite connective tissue lining, 22; single small cyst or cysts in a solid mass of ostitis fibrosa, 6; bone shell filled with solid mass of ostitis fibrosa without cysts, 7; multilocular cysts, 6; and a miscellaneous set, 12, including infected cyst, x-ray studies only, autopsy specimens, healed cysts and cysts in infantile scurvy. The periosteum is normal and there is little or no new bone formation unless there has been pathologic fracture or the cysts are of huge size and long duration. Cartilage may be present but "never in sufficient quantity to justify the conclusion that the cyst is due to the liquefaction of a primary or original solid area of cartilage." The fluid contents of the cyst are never distinctly hemorrhagic. Giant cells may be present in organized blood clot or more often near the lamellæ of the bone shell, but never (except one or two cases) in sufficient numbers to characterise the picture as giant-cell sarcoma. The second group, cysts due to conditions other than ostitis fibrosa, includes 20 cases as follows: Cysts in cartilage tumors or enchondromas, 4; pure myxomas with or without cysts, 5; cysts in giant-cell sarcoma, 4; cysts in arthritis deformans or ostitis deformans, 4; cysts due to subperiosteal hematoma with bony wall from ossifying periostitis, 2; and callus cysts, 1. The age of onset of benign cysts and ostitis fibrosa is with the rarest exception before twenty, and in the majority of cases before fifteen. Bloodgood notes in his experience medullary lesions in individuals under ten are either benign bone cysts with ostitis fibrosa or not very malignant giant-cell sarcoma, whereas between the ages of ten and twenty every variety of malignant medullary tumor has been met. Of the symptoms of onset, fracture predominates, pain is rarely prominent and swelling as a rule is usually late. Trauma seems to be the only prominent etiological factor and, although it cannot be proven, there is some justification in considering the possibility. Bloodgood holds that the disease is inflammatory, the medullary tissue being replaced by a new formation of connective tissue with or without cyst formation. The term "chronic osteomyelitis fibrosa cystica" or "solida" is, therefore, more appropriate than ostitis fibrosa. Curretting was performed in 38 cases; 33 have remained permanently well, 2 died from hemorrhage; 1 on account of hemorrhage was treated by amputation (Cotton), in 1 the cyst reformed and the leg amputated (Koerte), and in 1 a second curetting was done in two weeks (Kehr). Bloodgood strongly advocates curetting in every case, bearing in mind the danger of hemorrhage in very large cysts. Cysts are located most commonly in the humerus, femur and tibia, about in the order named. Cases have been reported with true bone cysts in the ulna, fibula, metatarsals and os calcis. Cysts in the phalanges have all proven to be pure myxomas. Twenty-seven cases of multiple cysts have been reported as follows: In Von Recklinghausen's disease, 12; in Paget's disease, 5; in osteomalacia, 6; in enchondroma, 2; in sarcoma, 1; and in mercurial poisoning, 1.

Of 13 personally studied cases of medullary giant-cell sarcoma, all are well and over 50% were situated in the lower end of the radius. Bloodgood feels inclined to curette at least as a first attempt before resorting even to resection. Repeated curetting does not seem to promote metastases, and now and then cures after two or more trials. Furthermore he believes that, if recurrence is to take place, it will do so in a few months. It is "imperative

to explore every medullary tumor seen in the x-ray or exhibiting itself clinically with swelling or pathologic fracture, before resorting to amputation." The duration of the tumors has been from five weeks to nine years, pain has not been prominent, expansion has been slow, abrupt and circumscribed. Although giant-cell sarcoma may break through its bony shell and infiltrate the soft parts, resection instead of amputation is at times justifiable. The appearance of the fresh tissue is somewhat that of currant jelly. Mixed with the red areas may be white areas, and areas mottled white and red. The consistency somewhat resembles "*Schmierkaes.*"

The term "bone aneurysm" is used to describe a hematoma in a very malignant medullary spindle- and round-cell sarcoma. Bloodgood has studied 3 cases, and he believes the condition in its early stage can be recognized by the hemorrhagic contents (never present in bone cysts and very rare in giant-cell sarcoma). The latter can be recognized by its characteristic tissue and small size of the cyst. Pulsation or bruit probably excludes benign bone cyst or ostitis fibrosa, but not giant-cell sarcoma. Partial or almost complete absence of bone shell is suggestive of the more malignant medullary tumor with central hematoma, but does not absolutely exclude medullary giant-cell sarcoma.

2. McCurdy considers papilloma, polypus, hypertrophy, epulis, chloroma, exostosis, osteoma, bone cysts, sarcoma and epithelioma. He then considers cysts and tumefactions from teeth, including impaction, delayed eruption, cysts from roots of developed teeth and cysts and tumors in connection with teeth during their development. The article is well illustrated with photographs, diagrams and case histories.

5. Janeway presents a case of resection of the ulna (5½ in.) for chondrosarcoma in which the defect was repaired by a piece of bone chiseled from the crest of the tibia of the same individual. Silver wire was used for fixation, and the periosteum of the transplant and that of the ends of the ulna were sutured. X-rays demonstrate increase in thickness of the transplant, callus formation at its upper end and direct union at its lower end. Janeway reviews the literature on osteoplastic operations, utilization of foreign bodies (celluloid, aluminum and gold plates, ivory), heteroplastic transplantation with and without preservation of vascular connections, and employment of decalcified bone chips and the iodoform plug. The author closes with a résumé of cases of autoplastic transplantation.

6. Stokes presents two cases of Madelung's deformity and analyzes 58 cases assembled from the literature. Both his cases were young girls (fourteen and fifteen), and in each both wrists were involved. The etiology of this silver-fork deformity is disputed; some hold trauma and occupation responsible; others, a primary one degeneration. The epiphyseal ends of the bones are irregular, excurvated and not completely developed. The end of the bone is smaller than normal and club shaped. The cartilages between the carpal bones and the epiphyseal cartilage are imperfect. Inasmuch as all symptoms disappear after about the age of twenty-five, palliative measures are indicated up to that age, when osteotomy may be performed. [T. W. H.]

2. Wechselmann has now increased his number of observations up to 503 cases of syphilis and parasyphilitic affections in which he has employed Ehrlich's new arsenic compound. He still considers it a remarkably effective remedy, not only as regards objective symptoms, but also for subjective symptoms. He has seen it work well where other treatment, such as mercurial injections, etc., have failed. Up to the present he has seen no ill-effects from its use in any cases.

4. Stieda takes up the reports of cases in which the hair was supposed to turn gray suddenly. He does not believe that the actual hair already grown changes color suddenly, and does not think the reported cases stand careful scrutiny. The sudden appearance of gray hair is due to the growth of new hairs without pigment. [C. F., Jr.]

1. Jager reports as the results of his experiments upon cats and dogs that the muscle bundle of Keith and Flack has no influence upon the relation between the contractions of auricles and ventricles. The Keith-Flack bundle lies at the junction of the superior vena cava and the auricle.

5. Finkelnburg, reporting on some cases of polyuria, considers that there are cases of true diabetes insipidus with brain lesions in which the concentration power of the kidneys is not destroyed. Nor does any diminution of power for concentration occur in polydipsia.

6. Joachim gives a very careful description of the morphological blood changes occurring in arsenic poisoning. One of the peculiarities is the extent to which the red blood count may be reduced without causing a fatal prognosis. It frequently went under 1,000,000 and as low as 710,000.

10. Bittorf has apparently written before on the adrenal gland, and in this article emphasizes by new cases certain points on the relation between Addison's disease and amyloid degeneration of the adrenals, thrombosis of the adrenal vein and hypernephroma. He also takes up a general discussion on the relation of adrenals to all pigmentation of the skin.

13. The regenerative power of the blood has usually been noted by the morphological characteristics. These authors have found a method of determining the regenerative power based on the fact that new red blood corpuscles absorb oxygen. The blood and oxygen under sterile conditions are mixed and put in an incubator. The old blood hardly changes the oxygen content, while regenerating blood changes it considerably. [C. F., JR.]

33. König, after a brief preamble in which he expresses his belief that the only cure for cancer is the knife, gives his idea of the proper treatment of cancer — not sarcoma — of the upper jaw. Because the last stages of this disease are so horrible, he advocates a truly radical operation, no matter what the cost. He has, in such operations, enucleated the eyeball and removed portions of the orbit until he came upon the dura mater itself. As there is very little glandular metastasis in cancer of this situation, there is some prospect of complete cure. Of 48 cases of epithelial cancer or alveolar adeno-carcinoma of the upper jaw, König can point to two who died without recurrence, eleven and nineteen years after operation, and to six still alive and well after post-operative periods ranging from ten to twenty-six years.

36. Reiterating a principle which has been advocated in his clinic since 1859, Freund advises operative treatment for those cases of thoracic immobility which show either stenosis of the upper aperture or dilatation of the lower chest. To the former deformity he thinks tuberculosis of the apices may be due, and advises section through the first rib if there is present a catarrh of the apex, or even a frank tubercular process, provided this process does not extend below the second rib. In dilatation of the lower thorax which has become fixed, emphysema is caused and, as a secondary result, circulatory and respiratory disturbances of a grave nature. For the prevention of these last, Freund advises excision of a portion of the cartilage of each of the lower ribs.

43. Propping's article on intra-abdominal pressure has a very practical application. He shows that when man is in an upright position, there is a decrease of pressure extending to negative in the summit of the abdominal cavity, while in the pelvis the pressure is increased. When the body is horizontal, there is a more equal distribution, but not so much pressure in any spot as there was before in the pelvis. Propping points out the relation of this fact to pelvic drainage. With the body in a half sitting position, and a wick to the pouch of Douglas, the fluid in cases of general peritonitis flows between the coils of intestines to the pelvis, and from there is driven out along the wick by the pressure of the abdominal contents, which is equal to 20 ccm. of water. This phenomenon holds only so long as the intestines are not adherent, — a period lasting from twenty-four to forty-eight hours after operation, — and will not occur unless the abdominal wound is closed tightly about the wick. [G. G. S.]

Obituary.

EMILY BLACKWELL, M.D.

DR. EMILY BLACKWELL has recently died at York Cliffs, Me., at the age of eighty-four. Dr. Blackwell, through a long life of medical activity, had been particularly distinguished as one of the earliest women physicians to gain a position of respect and prominence. She was born in Bristol, England, but her father and his family came to America in the early thirties and after a period of residence in New York removed to Cincinnati, Ohio. Dr. Blackwell, like her elder sister, began the study of medicine in 1848. She was refused admission at the Geneva, N. Y., Medical College, and in succession at ten other medical institutions, but in 1852 succeeded in being admitted to Rush Medical College in Chicago, from which, however, she was excluded the following year. She finally, however, was graduated from the medical school of Western Reserve University, Cleveland, in 1854. She then studied abroad for two years and returned to this country in 1856. With her sister, Dr. Elizabeth Blackwell, she established about this time the New York Infirmary for Women and Children, which, twelve years later, became a teaching institution and established a three years' course. It is said that this medical school was the first in this country to establish a chair of hygiene. Dr. Blackwell was, from its inception, one of its professors.

Dr. Blackwell's sister, Elizabeth Blackwell, died last May in England at the age of eighty-nine years. She is survived by another sister, a Unitarian minister at Elizabeth, N. J., and by Miss Alice Stone Blackwell.

Correspondence.

PARIS LETTER.

NOTES OF TRAVEL.

[From Our Special Correspondence.]

PARIS, Aug. 23, 1910.

Mr. Editor: I have just returned from a month's journey in the North, and find the papers, medical and political, particularly the latter, filled with Ehrlich and his 606. I presume that were I the model correspondent, who does the right thing at the right moment, I should adjourn to the library, get hold of the German papers, and send you a résumé of the question. But I am far from being the perfect individual referred to; beside this, other reasons cause me to lean towards procrastination: the weather is hot and the perusal of German medical literature is arduous; I have seen so much of Germany during my journey that I have had more than enough for the moment; and this very title, 606, puts me out of conceit with the entire subject. That a serious scientific man should not have been able to hit on a more suitable name for his product is remarkable; this shows either an unexpected lack of imaginative power, or else, — perhaps a wish to impress the public with the magnitude of his antecedent labors! So 606 will have to wait a little, so far as I am concerned.

I have been through Denmark and Sweden this year, completing the inspection of the Scandinavian countries that I have been carrying out during the past three summers, and the result of this visit has been to confirm the favorable impression this race has made on me everywhere, — a people of sterling qualities, honest almost to the ludicrous, truthful, straightforward in their dealings, simple in tastes, rough often on the surface, but with kindly hearts.

When I speak of their apparent roughness I mean that they lack many of the superficial nothings that prove so attractive to the traveler among the Latin peoples. Thus a Northman never says "Sir" or "Madam" except under the most exceptional circumstances; no matter what his position, — servant, porter, driver, conductor, — he gives you a plain "*Ja-ha*," or a "*Nei*," and acts as your equal. The northern language has, furthermore, no word for "please": when a Northman makes an effort to be polite, which does not come altogether easy to him, as he is very matter of fact with his fellow countrymen, to whom he is not unapt to speak in the second singular, he has to resort to circumlocutions. Again, his interrogative is a plain "What?"

But if you turn to him on the street or in the country in a dilemma and ask for information or help, there is nothing that is too much trouble for him to do to put you straight. He will give you all the necessary details, and then, if he suspects that you have not understood the unfamiliar tongue, he will turn and accompany you until he brings you to a point from which you cannot go wrong.

There is a curious thing about the Northman; he never expects that a stranger by any possibility is going to speak his language, and when by chance one comes along who does, he is so taken aback that at first he does not comprehend what is being said to him. And there is another very unexpected feature that you soon discover in traveling in Scandinavia: that your character as a foreigner is a title to public help, protection and, in many cases, even leniency in the matter of prices. When you are traveling in the countries of western Europe south of the Rhine, which we will call Latin to give them a name, and you have had a certain amount of experience, you can read the problem that is being worked out behind the impassive mask of the native's face when he thinks he has got hold of a raw tourist, especially of the American variety. The native looks on the easy-going American as a predestined prey sent by a mindful providence for the enrichment of his chosen people, and while he puts a few questions to you, to ascertain how much you know and just how verdant you are, he is in reality taking your measure and calculating just how many times the proper price you are likely to be willing to pay for the article in question.

The attitude of the native of Scandinavia is a totally different one. It is more or less this: "Here is a foreigner. It must be awkward to be in a country where you cannot speak or understand. I wonder what can be done to help him along." From this you will easily infer that the aspect of traveling in these different lands varies enormously.

The honesty of this people — for by Northmen I mean all that speak the Scandinavian tongues (they may call themselves Swedes, Norse, Icelanders, Danes, etc., but they are one race) — is something remarkable. When I say that I spent thirty days in Denmark and Sweden, constantly on the move, without being conscious that on a single occasion I was held up and "done" as a tourist, I speak the absolute truth. For a time I did think that I had been taken in at one place on a small scale, and felt rather sore over it as it spoiled what would otherwise have been a clean score, but fortunately on the boat coming home a Swede explained to me that what I had taken for an imposition was in reality a custom of the country, quite an unreasonable one, but still a custom accepted in the land. So this made me feel better.

When I reached Denmark, and all through Sweden, I had in my handbag two small newspaper wads of English and French small change, gold, silver and copper, ten dollars about in one, and fifteen in the other. This bag, which contained my everyday necessities, lay open in all the hotels, and was certainly not locked during the entire journey, and yet that money was not touched. In Italy a similar wad containing only a franc or two in French copper had disappeared inside of twenty-four hours.

I do not wish to dwell on this point too long, but the impression it made on me was very strong. On no occasion did any one give me bad money, or wrong change; now there is a well-known café on the Boulevards here, attended by foreigners in great numbers, where I will venture to assert positively that a raw American who cannot speak French and who tenders a twenty-franc gold piece in payment for his coffee, will stand an even chance of having a depreciated five-franc coin worked off on him among the change.

On no occasion were bills added up wrong, nor were there any doubtful charges; on the contrary, in several instances I had to remind different people of items left off. When I add, finally, — the finishing touch, — that even in the barbershops they limited themselves to doing what they were asked to do, and omitted to try the universal and familiar extortions, I think I can well close this side of the question.

I do not for one moment mean to claim more for these people than they deserve. I have no doubt that if, in a big center like Stockholm, you were to go to the starred hotel on Baedeker's list marked, "first class modern house, frequented by English and Americans," you would get all that you so richly deserve. But that is not my way of traveling. When I go to Sweden, or Italy, or any place, it is not with the purpose of meeting my estimable countrymen, or of eating the dishes I am used to the rest of the year. On the contrary, these are just the things I wish carefully to avoid. When possible, I arrange to reach a large center in the forenoon; I then leave all my things at the station and go on a prospecting tour. When I have found a quiet, *native* place on some side street, I arrange there for room and breakfast, and am then free to take other meals at the various restaurants as I please. In this way you get into the life of the people, the only point of interest in travel, and when once you find a nice house of this order they will be pretty certain to be able to give you other addresses in the places you are going to next.

With these people there is no haggling over prices. What they say they mean, and you can take it or leave it, as you see fit. Everything in the country, so far as we could see, has its figure, which is known and is generally plainly marked; this gives the stranger a sense of security that cannot be had in southern lands, where you are constantly under that disagreeable sensation that you are

being "done" in *some* direction, even if for the moment you do not see it.

In short, you do not have to live among the Scandinavians very long before you realize that you are dealing with white men, whose cerebral cells work along the same lines that yours do, and with whom it is possible to do business. That this race is really our ancestral stock, and that such good as there is in the American of English descent comes directly from them, does not admit of any question. The Keltish mixture in England seems to have been unimportant; and as for the Normans, what were they but Northmen who had married other Kelts in Gaul!

There is a custom so charming in Sweden that I cannot forbear from mentioning it, — the habit the servants have of courtesying when they receive a gratification on paying the bill. In many of the open-air restaurants the attendants are nice-looking young women of the better classes dressed in the national costumes; it is worth ten times the cost to see the courtesy you are there favored with for a small tip, and to hear the musical intonation of the "*tak so mykke*" (as it sounds), — thanks so much.

A Swede fellow I know in Stockholm — man with a sense of the humorous and unbecoming — wanted me to take a bath there. I needed a bath all right, there was no trouble about that, but I arranged to get one in accordance with our own ideas, explaining to him that my ancestors were all Connecticut Presbyterians and would have turned in their graves if they had seen me going in for a bath on Swedish lines. You have probably heard that in Sweden it is the general custom for the men to be soaped and scrubbed and rubbed by *women* in the public bathing institutions; it is done everywhere, and seems to them quite natural. That may be all right among Swedes, but I do not know how it would answer in other lands; I fancy it's a thing you have to be brought up to, and get accustomed to gradually.

I was struck, in Sweden and Denmark, as I had already been in Norway, with the quietness of the people. In Copenhagen, in some of the popular restaurants down at Tivoli where all of the tables were occupied, there was hardly more noise than in a first-class restaurant in England. Yet this people belongs to the Germanic race, and any one who has been in a popular restaurant in Germany, where every one is eating with mouths wide open and talking one incessant streak at the top of their voices, cannot help being forcibly struck by the difference. This is, of course, helped out by the fact that the northern tongues are infinitely softer and more musical than the German language; there is notably an almost total absence of the *sch* and *ch* sounds that occur so constantly in German and render it so very disagreeable to listen to. In these northern restaurants the clients take things very calmly. There is no calling for waiters, knocking on glasses, or ringing bells. The diner is content to wait his turn, and in doing this his character is put to some strain, as it must be admitted that the waiters up there are, as a class, the slowest and most inefficient corporation I ever came across.

I was greatly interested in a swimming and diving contest held at Stockholm, to which I was fortunately taken by my reprobate friend. I had heard of these before, but had never seen one and would not have missed it for worlds. The men were quite remarkable; the elaborate diving they did from a height that could not have been less than thirty feet was simply astonishing, and then a party of young women proceeded to do the same thing, tricks not so fancy, but done from the same height. To witness a slender lass of about fifteen skim out to the end of that plank and fling herself down that awful height without a tremor was indeed something to see and remember.

But the more practical part of the performance was the life-saving exercises. These were really admirable. How to approach a drowning person in the water and get him ashore is something every swimmer ought to know, and yet I wonder how many of our young men could do it, for it is anything but easy, and under usual circumstances is a most dangerous performance for the rescuer besides. I was struck with the method the Swedes adopt for fast swimming. The stroke is an arm-over-arm one, and the head is kept exactly in the axis of the body; this naturally brings the entire face under water, all you see being the swimmer's occiput. But at each alternate stroke, as the left arm goes under, taking the shoulder with it and turning the head to the right, the swimmer screws his face up a little to one side and you see for a second a huge mouth grabbing a supply of air. The entire race is run in this manner, face downwards.

Wherever we went in Scandinavia, as is the case also in the rest of Europe, the great majority of travelers were Germans. In Denmark they are estimated at eleven twelfths of the traveling public. As a Norse writer has put it, more pithily than elegantly, "For Germans, — like fleas and the wrath of God, — have we always with us!" They have altered their national traveling costume somewhat, or else the German of the North differs from his colleague you meet in such swarms in Switzerland and Italy. Venice, for instance, is now practically a German city; I shook the dust of the place from off my feet when at my last visit there I found that the street urchins were offering to pilot me back to the "*Markusplatz*"! Thus the German tourist of to-day in the North is apt to wear a blue serge costume and yatching cap; those hideous green knicker suits with the dicky Tyrolese headgear and feather that kept the hilarity of all Europe busy for so long a period seem to have altogether disappeared.

But whatever their dress, they are easy to recognize, wherever they are, and there is no place so remote but what you will find a German in Scandinavia. Wherever a man is making a fuss, or reaching for things, or shoving in ahead of others out of his turn, or in general doing something that others are not doing, and making himself disagreeable, you do not need to look at his yachting cap, his bespectacled and rapier-scarred face, or the circumference of his waist, to know what land he comes from. In all countries north or south, whether among people of his own kin or among the Latins, the German manages to make himself thoroughly disliked; there is not a dissentient voice on this subject. By universal consent he constitutes the type of the objectionable traveler whom every one could very well get along without.

One brief anecdote in closing. A friend of mine, a scholar from far-away Iceland, spent a year in a large German university town studying, and I asked him afterwards what he thought of the Germans. He replied without a moment's hesitation, "They are barbarians!" This fairly took my breath away, and I proceeded to ascertain whether there was not some *animus* in his opinion. But no. He said that personally he had nothing to complain of; that individually they had treated him well, but that as a race he considered them barbarians.

Now this man had been a shepherd boy in his youth, but a country clergyman had seen that he had an unusual mind and had had him educated. In the arrogant sons of the Fatherland on the Rhine to be called *barbarians* by a simple peasant from the heaths of a little island touching the Arctic Circle is one of those delicate ironies that has a particularly pleasing piquancy!

"*S.*"

DRESDEN, ROTHENBURG, BERLIN.

[*From Our Foreign Correspondent.*]

BERLIN, Aug. 26, 1910.

Mr. Editor: Despite the attraction of famous galleries and of the Passion Play, we left München and Oberammergau behind, like Yarrow, unvisited, and turned our faces from Heidelberg towards Dresden. The journey through Bavaria, broken by longer stops at Würsburg and Nürnberg, was beautiful for its extensive views of neat, cultivated fields and bits of woodland, and for its frequent glimpses of little red-roofed, walled towns perched among low hills or tucked away in tiny valleys, just like toy towns that children might play with. By far the largest and most perfect and most fascinating of these towns was Rothenburg, whose walls and towers and picturesque houses and up-and-down-hill streets are almost enough to drive an artist to distraction with admiration. Its inhabitants, too, seem unspoiled by the popularity which their town so deservedly enjoys, and preserve their quaint old local customs "unmixed with baser matter." Maxfield Parrish must have visited Rothenburg, for there are bits of it in many of his imaginative sketches. Indeed, the town is like the kind one sees in dreams, and a day spent in roaming its streets gives the same satisfying sense of long-

awaited fulfillment and realization that one experienced on seeing the pirates in "Peter Pan." Dreams do occasionally come true, after all, even in this world.

At Dresden there was much to see and much to learn, though of an entirely different kind. The city has an atmosphere of quiet refinement and culture that makes it remind one of Antwerp; and, as the capital of Saxony, it has also many public buildings whose massive beauty give it dignity and grandeur. Moreover, it is the greatest art center of Germany, and its picture-galleries in the huge Zwinger fill one with despair at their extent and richness. Casual visitors, like ourselves, cannot do better than to remember them for their greatest masterpiece, the Sistine Madonna, just as one remembers the Louvre for the Venus of Melos. Singularly enough, with all its wealth of what the Germans call *Kultur-Material*, Dresden has no university, the royal Saxon institution being at Leipzig. Perhaps it is for this very reason, however, that Dresden has attained its eminence; for, since no energy must be expended on the elementary instruction of many students, there is more opportunity for advanced individual work, and the city is, therefore, specially suited for post-graduate study in art or science. This seemed particularly true at the hospitals which we visited, whose spacious quarters and modern equipment give them unequalled possibilities as teaching clinics. The new Königliche Frauenklinik has the finest equipment of any such institution we have seen, and should be a model for hospital builders and administrators in America. Obstetrics and gynecology are, of course, here considered, in theory and in practise, as inseparably constituting a single department of medicine, as, indeed, they are considered throughout Europe. Surgically the obstetricians we met at Dresden seemed more conservative than those elsewhere in Germany. They do hebosteotomy to a considerable extent, but are still willing to employ forceps in moderate degrees of pelvic contraction, and when Cæsarean section is indicated, usually prefer the direct to the extraperitoneal route. We saw for the first time here the x-ray used in obstetrics. Considerable investigation on the subject has been done at this clinic, and the x-ray is here regarded as of established value in the diagnosis of multiple pregnancy, of tumors and of pelvic disproportions and deformities, though it is employed only near the end of pregnancy for fear of causing abortion. "One considers here the patient first," said the young doctor who escorted us, "and science second," a maxim that might well be more closely observed than it is in some institutions.

From Dresden we came to Berlin, where we are established on the Linden next the American embassy. In comparison with London and Paris, Berlin lacks always the potent fascination of an ancient capital, and at first one is tempted to think it a bit cheap as well as modern. But after one has seen its massive public buildings and *Denkmäler*, and has surveyed the golden magnificence of its numerous palaces, both in the city and at Charlottenburg and Potsdam, and has walked in the Tiergarten from Roland's Brunnen up the marble-statued Sieges Allée to the Pillar of Victory, crowned by its golden Borussia, and thence through the Brandenburger Thor up the Linden to the statue of Frederick the Great, one begins to realize what Berlin represents, and to give it its due place among the imperial cities. In the absence of antiquities, Berlin becomes simplified for sightseers, for in its present form it has not grown up at random, but has been created, and all its principal objects of interest are centrally grouped. The memories of Berlin are chiefly modern, too. Frederick the Great still dominates Potsdam, and, indeed, his personality invites study, for with his military system, his round table, his narrow sofa on which no one could fall asleep without falling off, his stepless stairs, his windmill, and his flute playing, his character certainly presents amusing and suggestive elements of paranoia. The old margraves and electors of Brandenburg are now little more than shadows, to a stranger at least; but the great tetralogy of men who made the empire and whose personalities are reflected most vividly in modern Berlin are the emperors William I and Friedrich III, the statesman Bismarck and the soldier Von Moltke. That was a stirring drama in which these men were the protagonists forty years ago, and the dominating spirit of Germany to-day seems to be the desire to glorify and perpetuate their achievement. Personally William I must have been a man of charming and democratic simplicity, for his palaces at Babelsberg and at Berlin still show a domestic and quiet taste that make them really homes. Friedrich III seems to have inherited his father's sweetness of character as well as the fortitude with which he bore his painful and premature death. The crown of thorns that surrounds the pedestal of his statue at Charlottenburg fitly suggests the suffering and disappointment that were his. Yet even the emperors are not more highly exalted than Bismarck, the latest of national heroes, whose genius most perfectly typifies that of the German race, and speaks to-day from every city of the empire and in every activity of the nation.

There are in Berlin so many opportunities of profitable study and observation that in a brief story one can hardly do any of them justice. Unfortunately we reached the city at midsummer, when its life was at low-water mark. Nearly all the leading medical men are away on vacation, and their juniors at the hospitals are naturally more interested in the opportunities thus given them than in the curiosity of foreign visitors. At the Königliches Charité Krankenhaus we were, however, most hospitably entertained, and saw much of interest. Obstetrically the enthusiasm here now is all for vaginal Cæsarean section, which is freely done for a large variety of indications, including eclampsia and rigidity of the cervix. Surgically the most interesting thing, for an American at least, has been to watch the working of stovaine spinal anesthesia, which is used here as a routine in all suitable cases. Operations under this method are certainly not painless, and usually necessitated the administration of a general anesthetic when the patient's complaints became severe. Indeed, without the stolid fortitude of the race, it hardly seems that spinal anesthesia could succeed except for brief and superficial procedures. For general anesthesia a mixture of oxygen, chloroform and ether is usually employed, and administered by means of the Dräger-Roth inhaler. We have had excellent occasion to watch the working of this apparatus, which has much to commend it. The ether and chloroform are aspirated drop by drop from separate chambers, at a rate which can be exactly controlled by the passage of a current of oxygen into a rubber bag in which the three gases are mixed and from which they are inhaled through a rubber tube and simple mask. This method has the advantages of economy, of constant accuracy and controllability of dosage, and apparently of safety, for no fatalities have yet been reported from its use, and, in all the cases which we saw, the course of the anesthesia was exceedingly smooth. It is customary to begin the administration with ten drops of chloroform and twenty of ether to the minute, increasing these to thirty and sixty respectively during the early stage of anesthesia, and decreasing to five and fifteen or twenty as soon as the patient is well under. The possibility of thus regulating at will the amount and proportion of each anesthetic, and the constant mixture of both with oxygen, seems to reduce general anesthesia to the simplest terms of safety and scientific accuracy.

It would have been possible for us to do much more in Berlin; but as our vacation nears an end we grow hungry again for England and the country and are leaving to-day for Hamburg, to sail thence for Southampton. We feel that it will be pleasant to be once more where every one talks our native tongue and shares somewhat our attitude towards life. Let this not be construed as a slander on Germany. The Germans are in many respects the most marvelous people on the face of the earth. They are the Romans of the modern world, as the French are its Greeks, and, though a little lacking in spiritual ideals, have preserved unabated the vigor and pristine energy of their ancestral Franks and Goths. They are to-day the most prolific and dynamic of civilized peoples, and bid fair to continue so, for the tramp of the

"Teuton feet that never tire"

shows as yet no sign of ceasing. We have learned much in Germany, of the people, their art, their science and their civilization. But the increase of our knowledge and admiration of the Germans has also served to confirm our respect and love for our own English-speaking people and their children wheresoever dispersed.

MEDICUS PEREGRINUS.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED AUG. 31, 1910.

GASSAWAY, JAS. M., surgeon. Granted one month's leave of absence from Aug. 7, 1910, on account of sickness.

GARDNER, C. H., surgeon. Granted one month's leave of absence from Sept. 1, 1910.

ANDERSON, JOHN F., passed assistant surgeon. Directed to proceed to Chicago, Ill., and Milwaukee, Wis., upon special temporary duty. Aug. 26, 1910. Detailed to attend the annua meeting of the American Public Health Association to be held in Milwaukee, Wis., Sept. 5-9, 1910. Aug. 26, 1910.

KING, W. W., passed assistant surgeon. Relieved from duty at Ellis Island, N. Y., and directed to proceed to Naples, Italy, and report to Surgeon H. D. Geddings for duty. Aug. 20, 1910.

MOORE, DUNLOP, passed assistant surgeon. Leave of absence for fourteen days from Aug. 10, 1910, amended to read ten days from Aug. 18, 1910.

MCCLINTIC, F. B., passed assistant surgeon. Granted six days' leave of absence from Aug. 22, 1910.

GOLDBERGER, JOS., passed assistant surgeon. Directed to proceed to Reedy Island Quarantine Station upon special temporary duty. Aug. 22, 1910.

VOGEL, CHAS. W., passed assistant surgeon. Leave of absence for fifteen days from Aug. 10, 1910, amended to read twelve days from Aug. 10, 1910.

MCLAUGHLIN, A. J., passed assistant surgeon. Directed o report to Surgeon Rupert Blue for duty. Aug. 13, 1910.

STIMSON, A. M., passed assistant surgeon. Granted fourteen days' leave of absence from Sept. 6, 1910.

FOSTER, A. D., passed assistant surgeon. Granted ten days' leave of absence en route to station. Granted thirty days' leave of absence from Aug. 30, 1910.

ROBERTS, NORMAN, passed assistant surgeon. Granted twelve days' leave of absence from Sept. 6, 1910.

FROST, W. H., passed assistant surgeon. Detailed to attend the meeting of the State Board of Health at Des Moines, Ia., Aug. 17, 1910. Aug. 15, 1910. Directed to proceed to Britt, Ia., upon special temporary duty. Aug. 25, 1910.

GRIMM, R. M., assistant surgeon. Granted four days' leave of absence from Sept. 1, 1910.

KNIGHT, CARLISLE P., assistant surgeon. Relieved from duty at Buffalo, N. Y., and directed to proceed to Ellis Island, N. Y., and report to the Chief Medical Officer for duty. Aug. 17, 1910.

BOYD, FRANK, acting assistant surgeon. Granted twenty days' extension of leave of absence from May 27, 1910, on account of sickness.

MCDANIEL, S. E., acting assistant surgeon. Granted five days' leave of absence from Aug. 14, 1910, under paragraph 210, Service Regulations.

MCGINNIS, R. H., acting assistant surgeon. Granted nineteen days' leave of absence from Sept. 11, 1910.

ROBERTSON, HERMAN, acting assistant surgeon. Granted six months' leave of absence without pay from Sept. 1, 1910.

RODMAN, J. C., acting assistant surgeon. Granted seven days' leave of absence from Aug. 30, 1910.

ROSELLO, M. M., acting assistant surgeon. Granted five days' leave of absence from June 27, 1910, under paragraph 210, Service Regulations.

RUSH, JOHN O., acting assistant surgeon. Leave of absence granted Aug. 6, 1910, amended to read fourteen days from Aug. 13, 1910, with pay, and twenty-eight days from Aug. 27, 1910, without pay.

GAHN, HENRY, pharmacist. Granted sixteen days' leave of absence from Aug. 22, 1910.

HERTY, F. J., pharmacist. Granted one day's leave of absence, Aug. 22, 1910, under paragraph 210, Service Regulations.

BECK, J. E., pharmacist. Relieved from duty at Honolulu, Hawaii, and directed to proceed to Savannah (Quarantine), Ga., and report to the medical officer in command for duty and assignment to quarters. Aug. 20, 1910.

BIERMAN, C. H., pharmacist. Granted four days' extension of leave of absence from July 26, 1910, on account of sickness.

OTT, C. R., pharmacist. Directed to report to Surgeon P. C. Kalloch, chairman board of medical examiners, to determine fitness for promotion to grade of pharmacist of Class 2.

WOLFE, J. A., pharmacist. Granted six days' leave of absence from Aug. 23, 1910, under paragraph 210, Service Regulations.

WEITGENANT, WAYNE W., pharmacist. Directed to proceed to Chicago, Ill., and report to the medical officer in command for duty and assignment to quarters. Aug. 25, 1919.

APPOINTMENT.

WAYNE W. WEITGENANT appointed a pharmacist of the third class Aug. 23, 1910.

RECENT DEATHS.

DR. JAMES H. MCINERNY, of New York, died from cardiac disease on Sept. 5, at his summer residence at Mount Vernon, Westchester County, N. Y. He was born in 1860 and was a graduate of Yale and of the College of Physicians and Surgeons, New York. At the time of his death he was assistant surgeon to the General Memorial Hospital, New York.

DR. FRANCIS H. STUART, a prominent practitioner of Brooklyn, N. Y., died from cardiac disease on Sept. 4. He was a native of Logansport, Ind., and sixty-two years of age. Dr. Stuart was attending physician to St. Mary's Hospital and surgeon to St. Peter's and the Brooklyn Hospitals.

DR. FREDERICK STEFFEN, of College Point, Borough of Queens, New York City, died from cerebral apoplexy, on Sept. 9. He was fifty-two years of age, and had practised at College Point for the last twenty-two years.

THE PLACE OF TUBERCULIN IN THE IMMUNIZATION OF UROGENITAL TUBERCULOSIS.*

BY GEO. P. SANBORN, M.D., BOSTON.

THE clinical facts of immunity and recovery from infectious disease, and artificial protection by vaccination, in conjunction with data obtained from research as to the reasons for these phenomena, furnish sufficient evidence for the conclusion that the body is possessed of what may be termed an immunizing mechanism. Under normal conditions it appears to be capable of directing itself to the destruction of bacteria as they enter the body, or, in the case of its failure to repel the initial attack, capable of intense specific reaction, humoral and cellular, directed against the bacteria as they cultivate themselves in the tissues.

As might be expected, the only real success that has been achieved in cure of and protection against infectious disease has been based upon intelligent appreciation that therapeutic measures are without avail unless they minister in some manner to natural and efficient functionating of cells which constitute the immunizing mechanism. The intent is to supply some deficiency which these cells are unable to furnish; to remove some obstacle to their specific action against the infectious process; to furnish stimulus to the cells for the formation of specific antibodies, when such is lacking; or stimulus of some bacterial derivative which shall enable the cells to furnish, through this artificial measure, specific antibodies, resulting in protection or artificial immunity against a specific disease. For example, in acute infections such as typhoid and pneumonia, years of unavailing empirical treatment have yielded nothing in the way of specific medication comparable to antitoxin in diphtheria, with the result that at present the best treatment is believed to be that which keeps hands off, supports and nourishes the patient, to the end of conserving so far as is possible proper functionating of the body cells. The same may be said of pulmonary tuberculosis, in which, by hygienic measures, we afford every opportunity for efficient cellular reaction against the infection. By these measures we promote the efficient functionating of the cells, particularly, we hope, those which constitute the immunizing mechanism.

We have in treatment of diphtheria by antitoxin an example illustrating the supply of a specific antitoxin at a time when, in the natural course of events, the body's cells fail in elaborating a sufficiency.

In surgical treatment of localized tuberculosis by excision of caseous material and drainage of pus, we have an example of removal by artificial means of an obstacle to the efficient working out of the immunizing process. By these measures circulation is to some extent re-established, and the efficient application of antibacterial substances therein contained is made possible.

Localized tuberculosis associated with fever cannot be looked on as really local. The fever is the result of the entrance and disintegration of bacteria and poisons in the blood stream. In this we find reason for the inefficient working out of the natural process of immunization. Evidence obtained through opsonic index observation shows that in these cases excessive auto-inoculation is taking place, and indicates that the immunizing mechanism is being over-excited and, therefore, fails in efficiency. Extirpation of diseased tissue or drainage of pus is commonly followed by a drop in temperature. Recovery and subsequent elevated condition of the opsonic power indicates that by this measure auto-inoculation has been controlled, the immunizing mechanism has recovered from its over-excited condition, and favorable response in the production of antibodies is obtained. Thus in eliminating auto-inoculation we have removed an obstacle to the efficient working of the immunizing process.

Again, in *afebrile* tuberculosis, when the lesion is drained or excised, we aid the immunizing process by removing the focus which is responsible for the continued and characteristic deficiency of the blood stream in opsonic power. This deficiency appears to be the result of continued contact of the blood stream with the outskirts of the infected focus, so that finally it loses, by local combination with the bacteria and their poisons, considerable of its antibacterial substances. At the same time, it is to be supposed that the immunizing mechanism lacks sufficient stimulus to the formation of antibodies, on account of the walled condition of the focus of disease and the inability of the blood to take up a sufficiency of bacteria, to constitute an auto-inoculating stimulus which shall result in an immunizing response. At any rate, opsonic determination has shown that, in localized tuberculosis of the *afebrile* type, the opsonic power is consistently low, a fact which indicates absence of auto-inoculation. Consistent with this supposition are the marked elevations in opsonic power after stirring up of the focus of infection by surgical measures, which fluctuations can only be due to entrance of bacteria or poisons into the circulation, and their effect upon the body cells. It is perhaps needless to say that beyond the advantage to the functionating of the immunizing mechanism due to extirpation or drainage, removal of a badly infected organ or mass of tuberculous tissue safeguards the rest of the body from metastatic infection. Secondly, it removes a mass of tissue which, under ordinary conditions, the body is unable to cause to resolve.

Unfortunately in genito-urinary tuberculosis the many avenues for extension of the disease process renders it commonly impossible completely to extirpate all diseased tissue. Nevertheless, since it has come to be recognized that post-operative hygiene is an important aid, it has been found that frequently the body, relieved of its major focus of disease, is able to react to the obliteration of minor foci, at least to the extent of affording clinical recovery.

If complete extirpation of disease tissue were

* Read by invitation before the American Urological Association, winter meeting of the New England Branch, March 8, 1910.

possible, no further measures would be needed than could be furnished by surgery and hygiene, but even in tuberculous glands of neck, for instance, in spite of apparently excellent opportunities offered to careful and clean dissection, how often does recurrence prove that one can never count on complete extirpation.

While surgical measures have, something in the manner stated, a distinct place in a rational scheme of immunization, they do not completely fulfill indications. No further evidence in support of this is required than chronicity after surgery has done its utmost. In fact, on the whole, surgery is, for the reasons stated, in large numbers of cases, merely palliative. The immunizing mechanism still lacks something to render it efficient as leading to cure.

Through his study of bodily reaction against infection by aid of the opsonic index Wright has furnished us with the rationale of efficient treatment at this point. As has been suggested before, opsonic determinations have shown that in chronic localized tuberculosis, and in febrile tuberculosis, after surgery, by eliminating auto-inoculation, has rendered the lesion localized, the tuberculotropic power of the blood stream is, in the vast majority of cases, greatly deficient. This deficiency may with reason be attributed to the segregated condition characteristic of chronic tuberculous foci, and consequent impossibility of the blood's receiving sufficient bacterial stimulus, which, when applied to the cells, whose function is to produce specific antibodies, would be calculated to incite their formation. On the other hand, it has been shown that, where the body is making a satisfactory response to infection and is progressing toward recovery, the opsonic power of the blood is usually in an elevated condition.

It is reasonable to make deduction that chronicity is in part due to this low antibacterial power of the blood stream, which in turn is due to a deficiency of bacterial stimulus. In part, also, it would appear that chronicity is favored by poor circulation of blood in the infected focus, and difficulty of applying the full antibacterial power of the blood stream against the bacteria barricaded, as it were, therein. We should expect, however, that a blood stream, high in specific antibacterial power, would be more efficient under any condition than would be the case if the antibacterial power were low. At any rate, it should be fairly certain that a blood stream of high antibacterial resistance would render metastastic infection less apt to occur. These considerations appear to be borne out clinically, in that, in the majority of cases, clinical improvement begins when a low opsonic power gives way to a heightened opsonic power following the careful exhibition of tuberculin.

We find, then, that by the use of tuberculin we furnish stimulus in default of which the immunizing mechanism does not proceed to the formation of specific antibodies. We see reason for this in the segregated condition of the infected focus and resulting absence of auto-inoculation. We furnish this stimulus by the injection of tuberculin, and we consistently find that the opsonic power of the blood becomes elevated. This is sufficient evidence of response to the injected vaccine. Coincidentally with favorable response, as indicated by opsonic determination, clinical improvement is commonly to be noted.

These suggestions as to the probable manner of the accomplishment of surgery, hygiene and tuberculin as promoting the efficiency of the immunizing mechanism, furnishes a working basis for rational therapeusis. In genito-urinary tuberculosis, they (surgery, hygiene and tuberculin) constitute the limit of effective treatment based on present knowledge. In other forms of tuberculosis, it may be possible to introduce a fourth measure, namely, determination of blood to the infected focus. It is obviously impossible to derive the greatest advantage from a blood stream rendered high in its antibacterial potency, unless the usual impaired circulation in and about a tuberculous focus can be improved, or in some manner the blood be brought into contact with the bacteria. In tuberculous infections superficially located, application of heat may increase the active circulation, and Bier's bandage and cupping may force the blood serum into the focus of infection. In genito-urinary tuberculosis such measures are, with rare exception, impossible of application.

With foregoing considerations in mind, localized tuberculosis should no longer be considered as a purely surgical problem, with adjunct measures to be applied *to render the surgical measure more efficient*, but rather *as problems in immunization*, in which surgery, hygiene, tuberculin and other measures should be made use of only as they serve to fulfill rational indications as leading to efficient working of the body's immunizing machinery.

What, then, should be our expectation in the practical use of tuberculin in genito-urinary infections? First, when extirpation has been rendered as complete as possible, and after the effect of the auto-inoculation induced by the surgical procedure has worn off, we anticipate that tuberculin will render the blood stream more efficient in destroying bacteria that may enter it from the focus of infection. Secondly, that it will tend to limit the spread of the infection. Thirdly, that after a long period, from months to several years, of careful use of tuberculin, the blood stream may eventually either obliterate the focus or enable walling off to be complete. We may anticipate, in case of ulcers of bladder mucous membrane, where circulation is better than in infected organs or masses of tissue, a more ready yielding to treatment. This appears clinically to be a fact.

We do not expect that a blood stream high in antituberculous power from the use of tuberculin will induce resolution of caseated and disintegrated organs and masses of tuberculous tissue.

PRACTICAL INDICATIONS FOR TUBERCULIN.

(1) In case of organs involved which cannot be extirpated, such as the bladder. (2) In case of any

organ in which tuberculosis is very early and in which disintegration has not taken place to any considerable extent. (3) In case of tuberculosis of both kidneys where it is deemed unwise to operate either. (4) Postoperatively in case that it is apparent that all tuberculous tissue was not removed or where organs that were involved could not well be extirpated. (5) In any case where bladder involvement is present. (6) In any case where there is a suspicion that tuberculous tissue has been left behind.

CONTRA-INDICATIONS FOR TUBERCULIN.

Persistence of temperature after drainage usually indicates that there is still some pocket that has not been reached. If such a possibility is eliminated, and temperature still persists, in the absence of pulmonary involvement which should always be sought, tuberculin may be cautiously used. Tuberculin should not be used in febrile cases until these questions are settled. If there is active pulmonary involvement, if tuberculin is given at all, dosage should be modified according as the pulmonary condition requires.

Tuberculin is never a panacea, it has no resemblance in its action to antitoxin and can never be counted on as an efficient measure of last resort when the patient has one foot in the grave

DANGERS IN THE USE OF TUBERCULIN.

Practical danger of overdosage has been illustrated again and again. The fact that too frequent or too large dosage, instead of raising the antituberculous power of the blood, tends to lower it, should be sufficient evidence that great care must be used. The unfortunate results attending its first application in the treatment of pulmonary cases furnish clinical evidence of its danger. It is difficult, in a given case of localized tuberculosis, where the lesion is not under the eye, to note its effect. Absence of constitutional symptoms subsequent to inoculation does not mean that tuberculin is doing no harm. It may serve to maintain blood in a state of lowered anti-bacterial power, and its effect be manifested by persisting chronicity, by gradual spread, or, finally, and perhaps suddenly, the appearance of new foci of infection. In urogenital tuberculosis, the difficulty of determining whether an organ is too much involved for the use of tuberculin, as against surgery, renders it absolutely essential that these cases should be given tuberculin always at the instance, and under the critical supervision of, the surgeon. Otherwise, the problem for tuberculin may, at the start, be extremely beyond its scope.

METHOD OF GIVING TUBERCULIN.

In giving tuberculin, the writer has for three years followed closely the method of Wright, as being rational, conservative and safe. The keynote of this, the opsonic method, is to so grade dosage that no generalized reactions may be produced; to achieve a succession of immunizing responses calculated to maintain the opsonic power as continuously elevated as possible. By it, we never reach dosage of toxic proportion, save by error; we arrive at large dosage only after a considerable time, during which we have at no time so seriously reduced the tuberculo-tropic power of the blood as to produce severe constitutional symptoms, with their attending dangers. The danger of such lowering of resistance probably varies in different cases, but in many it may conceivably be a distinct menace to the patient in rendering development of other foci possible and favoring extension of present foci.

In practice, this means that initial dosage of tuberculin is minute, varying from 1-50,000 to 1-20,000 mgm. of bacillary substance; in febrile cases, 1-100,000 mgm. to 1-50,000 mgm. Doses are are given at weekly intervals and increased so that at the end of six months or a year dosage may be from 1-1,000 to 1-5,000. A slight rise in temperature, increased frequency of micturition, increase of pain, headache, malaise, nausea, chills, occuring the first day or two after inoculation, are indicative of toxic dosage, and these conditions are found to be correlated with marked reduction in the opsonic resistance. When such symptoms occur, we should always await spontaneous improvement before again inoculating, and then start with a considerably smaller dosage. The production of a small nodule at the point of inoculation is, in the writer's experience, indicative that limit of tolerance is being approached.

In afebrile cases, and those in which changes in the local lesion cannot be observed, there may be total absence of subjective and objective evidence that resistance is being lowered by dosage used. In these cases, we may have positive evidence that tuberculin is doing good in the sense of well being following inoculation and increase in weight. In such cases, we base our increase in dosage on previous experience in treatment of other cases.

The efficacy of tuberculin as an aid in rational immunization can only be judged by consideration of each case separately. Its efficacy cannot be judged in terms of cure at the present time, or until much larger numbers of cases have been treated and reported. The period of treatment is, of necessity, of so long duration, one or two years or more, that complete cases must necessarily at this time be few. Although the writer has a number of cases of chronic tuberculosis of the genito-urinary tract under treatment, only those that are more or less complete are recorded. The admirable article of Thompson Walker[1] on the subject has been taken as a basis for classifying the different tuberculous infections of the genito-urinary tract, and his cases and observations will be frequently referred to as being the products of an unusually extensive experience in treatment of genito-urinary tuberculosis, and in use of tuberculin as a therapeutic measure.

Tuberculin treatment should never be instituted in urogenital tuberculosis until thorough investigation as to the extent of involvement has been made and the question of extirpation has been

[1] Practitioner, London, May, 1908.

decided by the surgeon trained in special methods of diagnosis and treatment. Neither should tuberculin be given by the surgeon except on basis of previous experience in specific immunziation.

RENAL TUBERCULOSIS.

Expectation that exhibition of tuberculin in extensive renal involvement, associated with disintegration and extensive caseation of the kidney, will take place of extirpation of the organ is entirely unfounded. It may reasonably be expected that proper use of tuberculin may maintain the blood stream in a condition of increased resistance to the tubercle bacillus, but, both in theory and in practice, it is unjustifiable to risk the patient's life by leaving unmolested a disintegrated, useless kidney on expectation that the blood stream will, by means of its high antituberculous power, be able to produce resolution. It is obviously impossible to transfer antibacterial elements of the blood stream into a mass of caseated material, or even to conceive of a sufficiently active circulation in the infected tissue surrounding such a mass of caseous material, to cause destruction of tubercle bacilli present and resolution of disintegrated, infected tissue. Involvement of both kidneys, if extensive, may contra-indicate extirpation of either. The use of tuberculin in such cases has been found to produce distinct amelioration in pain, frequency of micturition and temperature, and may be considered a decidedly useful measure for temporary relief, although from the start such cases are beyond hope of cure.

A case of this type is reported by Walker,[2] and briefly is as follows: After three weeks' treatment with tuberculin, pain and hematuria disappeared, and frequency of micturition diminished. Temperature fell to 99° F.; weight increased. After six weeks no bacilli were found in the urine. After three months the patient died of renal failure.

When occlusion of the ureter results in accumulation of pus under pressure, as suggested by Walker, there can be no question of the inadequacy of tuberculin for a cure. When the ureter is involved there is always danger of occlusion, particularly if tuberculin is used. This danger depends on the common induction of a "focal" reaction by tuberculin, which, in the case of an infected ureteral mucous membrane, by automatically induced inflammatory reaction, may produce such swelling of the mucous membrane that occlusion may result. Focal reaction may be avoided generally if small dosage of tuberculin be adhered to.

These considerations further suggest the importance of careful investigation by the trained surgeon, and necessity for his constant watchfulness in treatment of such cases.

Tuberculin should be of the most advantage in the early stage of renal tuberculosis. It is uncommon, however, to arrive at a diagnosis at this early period, because the first evidence noted by the patient, such as cystitis, may not appear until long after the disease has gained considerable headway in the kidney.

Given a diagnosis of tuberculous kidney in its early stage, the question of tuberculin, as against extirpation, cannot be settled until more cases are reported with ultimate results and compared to those obtained by extirpation. A trial of tuberculin cannot be dangerous if it be administered carefully. The question of extent of involvement, if decided, will largely determine the advisability of tuberculin, and must be decided by the surgeon.

Walker reports treatment of an apparently early case as follows:

A history of sudden attack of pain in kidney, shooting into groin and testicle, followed by dull renal ache. Passed blood. No bladder symptoms. Pott's disease twelve years before with cold abscesses. At about the same time amputation of left foot for tuberculous disease. Kidneys not tender; right slightly enlarged. Tuberculin 1-250 mgm. once a month, gradually increased to ½ mgm. "Almost from the first weight increased. Blood has not appeared in the urine since treatment commenced." For eight months the pain in the kidney continued troublesome. After that, it suddenly diminished, until January, 1906 (seventeen months' treatment), when it disappeared. Reduction in the dosage of 1-1,000 mgm. was followed by a noticeably increased pain. In July, 1906, dose was raised, and in February, 1907, patient stated that he had had no pain since the increased dose. There was less pain with larger doses.

Carmalt Jones reports the cases of renal tuberculosis treated in Wright's clinic. Of cases treated, 2 were considered cured, 2 "better," 2 "somewhat better," and 1 dead.

The writer has used tuberculin in 1 case of renal disease which was thoroughly investigated and in which the organ was considered to be not sufficiently disintegrated to demand extirpation. The patient, J. R., fifty-five, male, admitted to the Boston City Hospital service of Dr. Paul Thorndike, Nov. 2, 1908. This case is partially recorded by Cunningham, of Boston, in the BOSTON MEDICAL AND SURGICAL JOURNAL, March 18, 1909, pp. 340–343. A brief résumé is as follows:

December, 1907, noticed increased amount of urine. Since then has urinated ten times at night and urine has been cloudy and thick. For the past ten years had urinated three or four times each night. Six months ago had an attack of polyuria, rising as many as twenty times a night. This lasted three days. No pain referable to the urinary system, and no blood in the urine. There has been little loss of weight, but occasional dull aching pain in small of back.

Physical examination generally negative. Sallow complexion. No external sign of disease, save cloudy urine.

Urine examination, pale, turbid, specific gravity 1016, acid, albumen slight.

Sediment considerable, consisting of much pus, medium round cells, bacteria, triple phosphate crystals. Occasional normal blood corpuscles. Some squamous epithelioma.

Cystoscopic examination (Dr. Cunningham), Nov. 6, 1908. Voided urine cloudy. No residual. Bladder capacity, 9 oz. Bladder easily washed clean. Bladder wall and trigone normal. Right ureteral orifice normal.

[2] Practitioner, London, May, 1908, p. 723.

Ejaculations of urine at intervals of thirty-five seconds. Ejaculated urine very cloudy. Left ureteral orifice normal; ejaculated clear fluid, rate forty-five seconds. Both ureters catheterized; specimen from right kidney very cloudy, in same degree as voided urine; specimen from left ureter normal in appearance.

Macroscopic appearance of specimen from right kidney, and also of voided urine, when shaken, was that of milk. After settling there was a white sediment ½ to 1 inch thick. Supernatant fluid remained cloudy.

Report of the Pathological Department, Boston City Hospital, on examination of the catheter urines:

Right ureter very cloudy. Smears and cultures show B. coli in abundance and few staphylococci. Much pus, mostly polymorphonuclear leucocytes and some red corpuscles.

Left ureter slightly cloudy. Cultures with B. coli and staphylococci. Occasional pus cells.

The urine from the right kidney had all the characteristics of that voided from the bladder, while that from the left kidney was straw-colored, very slightly cloudy, and had little sediment. Tubercle bacilli were sought in stained smears, but none were found.

X-ray examination, Nov. 5, 1908. No evidence of renal or vesical calculi.

Diagnosis of pyelitis was, therefore, made. The colon bacillus was considered as a predominating cause. The kidney involvement was not considered sufficiently serious to require extirpation of that organ, and it was decided to make the attempt to immunize the patient by the use of vaccine prepared from the culture of the colon bacillus obtained from the urine. The patient's serum agglutinated this colon bacillus in dilution of 1-128, thus proving actual infection.

Common association of colon infections with tuberculous conditions was considered, and a guinea pig was inoculated intraperitoneally and in the groin with urine sediment.

Inoculation of colon vaccine, started Nov. 9, 1908, was given three times a week at first, and later twice a week. After the fourth inoculation, the urine assumed a distinctly straw color, and there was scarcely ¼ inch of sediment. Frequency at night reduced from six to three times.

Dec. 15, 1908, urine after sedimentation was of normal straw color and nearly clear. At times the amount of sediment was barely sufficient to cover the bottom of an 8-oz. bottle; at times there was a ¼-inch layer. At the end of December, 1908, after two months' treatment, there were but few colon bacilli in the sediment or supernatant urine.

Frequency of micturition did not continue to lessen, in fact, again reverted to five or six times at night, and every two hours or so during the day. General condition did not show improvement commensurate with clearing of the urine. Loss of five pounds during second month of treatment; moderate exercise produced exhaustion.

Lack of improvement generally brought again to mind the possibility of tuberculosis. The Von Pirquet skin test was performed Jan. 7, 1909, and was brilliantly positive. In the absence of evidence of tuberculosis elsewhere, in consideration of history, failure to improve when the condition of the colon infection actually became better, and positive cutaneous tuberculin test, brought prominently to mind tuberculosis as the best explanation of the condition.

Beginning Jan. 7, 1909, Tuberculin R. was injected at weekly intervals, initial dosage 1-20,000 mgm. (bacillary substance). During the first four weeks patient gained 6 lb., and stated that he felt stronger, had better appetite, and could hold his urine a longer period.

On Jan. 29, 1909, the guinea pig inoculated Nov. 12, 1908, died. Autopsy showed a generalized miliary tuberculosis, and smears showed tubercle bacilli in large numbers.

From Jan. 7, 1909, till April 27, 1909, Tuberculin R. was given weekly, dosage reaching 1-7,000 mgm. but once, usually 1-10,000 mgm. or less. There were no subjective symptoms produced after any inoculation. During early April the patient began to complain of dull pain in right lower abdomen. In the latter part of April complained of profuse perspiration and chilly sensations. Temperature occasionally 100. A mass was felt in right lower quadrant and patient was referred back to the surgeon.

He was operated June 1, 1909, by Dr. Munro, who kindly furnished notes of the case.

"Filling whole right flank, from 2 inches below costal margin to below iliac crest and extending to within 2 inches of median line, a hard, rounded, immovable, tender tumor."

June 1, nephrectomy, Dr. Munro. He found "large kidney full of abscess cavities with pus and caseous material. Pedicle thick and brittle. Ureter traced below brim of pelvis and found small and not thickened."

Fifteen days later patient was out of bed; next day chill, restless. Wound opened; no pocketing found.

Developed high respiration, pulse and temperature. Right lobar pneumonia. Died June 18, 1909. No autopsy.

Pathological report, kidney-tuberculosis.

There are several points of interest in this case. First, as to diagnosis; it illustrates the necessity of bearing in mind the possibility of tuberculosis as the basal process in a case of this type. Tuberculosis is so commonly associated with colon infections that, in the absence of tubercle bacilli in smears, animal inoculation should be carried out.

Second, it shows it may happen that a kidney is seriously involved and disintegrated, without offering evidence that such is the case.

Third, consequently, it further shows that tuberculin treatment may at any time have presented it, — an impossible problem. It is absolutely unjustifiable to expect that tuberculin, by raising the anti-tuberculous power of the blood, should achieve resolution of such an extensively involved organ, or even to conceive that the blood, no matter how efficient it is rendered in antibacterial power, should be able to transfer its antibacterial elements into masses of caseated tissue. Tuberculin may be counted upon to increase the efficiency of the body as against the tubercle bacillus, but it cannot assume the place of surgery in the immunization of these cases.

The efficiency of tuberculin cannot be judged by the outcome of cases of this type.

VESICAL TUBERCULOSIS ASSOCIATED WITH RENAL INVOLVEMENT.

Renal tuberculosis is commonly complicated by secondary bladder tuberculosis. It may be difficult to say which is the original seat of infection, bladder or kidney. Cystitis associated with renal disease may clear up after extirpation

of the diseased organ. Walker (*loc. cit.*) states that in some cases cystitis appears to be due, not to actual tuberculous infection of the bladder, but to irritation caused by the deposits from the kidney. In claiming cure of tuberculous cystitis by removal of the kidney, this possibility must be borne in mind.

When, in spite of extirpation, cystitis persists, use of tuberculin is indicated. Walker concludes that it is a valuable adjunct to operation. He reports the following case (*loc. cit.*):

Patient had constantly aching left kidney eight months. Worse in morning, aggravated by exercise. Nocturnal micturition for six months. Blood in urine. Frequency half-hourly in day, two-hourly at night. Left kidney large and tender. Cystoscope showed general tuberculous cystitis, left ureter retracted. One month later large tuberculous left kidney removed, and a month later tuberculin begun. During twelve months' treatment there was increase in weight, frequency of micturition became hourly instead of half hourly, pain less; improvement was slow but undoubted.

Brief summary of a case of this type treated by the writer is as follows:

Female, forty-seven, married.

Increased frequency for over five years. Three months before operation cystitis became severe; incontinence of urine; much pus and many tubercle bacilli found.

At operation right kidney and ureter were found to be extensively tuberculous and were removed.

When seen by writer, two months after operation, there was a free discharge from two operative wounds. Urine foul, cloudy, contained pus and tubercle bacilli and large numbers of colon bacilli. Micturition during the day every twenty minutes; at night, ten or fifteen times. Excessive vesical pain. Temperature 100 to 102° F. Prostration, emaciation. Bad prognosis given by the attending surgeon.

Tuberculin R. was given at weekly intervals, beginning with 1-20,000 mgm. (bacillary substance). Temperature normal after two weeks. Dosage of 1-8,000 mgm. at end of two months. General condition, strength, weight, appetite, showed at this time a decided gain. Pain and frequency did not improve commensurately. A colon bacillus isolated from urine was agglutinated by the patient's serum at a dilution of 1: 28. Colon vaccine prepared and injected twice a week at first. Initial dose, 10,000,000.

Before the end of two weeks there was less pain and frequency; the urine appeared a little less cloudy and less foul. In the second month of treatment with the combined vaccine the urine became comparatively clear. After six months from the start, the wounds had healed; the urine, no longer foul, contained very little sediment. Urination every two hours in day, less often at night, associated with very slight burning. At this time patient had been up and about increasingly for two months; had gained considerable weight.

At the time of writing (March, 1910) the patient had received tuberculin weekly twenty-one months with occasional breaks. The maximum dosage, 1-2,000 mgm. For six months colon vaccine was given, at first twice weekly and later once a week. Maximum dosage, 60,000,000. It was omitted about a year ago. The urine sediment was slight and no colon bacilli were to be found on recent examination. It still contains tubercle bacilli, as recent inoculation experiment proved. Micturition every three to five hours, occasionally once or twice at night. No pain. Gain in weight approximated at 30 lb. Is able to attend to household duties and to go about without discomfort. She states that she feels better than she has for several years.

There are certain features of this case that are worthy of note: First, immediate improvement in cystitis following administration of colon vaccine, there having been no improvement in this regard during two months of exclusive tuberculin treatment; second, the fact that colon bacilli were very few in the urine after six months of treatment with colon vaccine; third, that, although the maximum dosage of colon vaccine was but 60,000,000, and the last dose was given approximately a year ago, immunity established has apparently continued to the present time; fourth, the presence of living tubercle bacilli in the urine indicates that the process is still active somewhere, but the patient's excellent condition, and absence of temperature, indicates that she has at present a well-defined degree of immunity; fifth, the presence of these bacilli indicates that every possible measure should be made use of to increase the patient's resistance, and, particularly, that we must maintain the antituberculous power of the blood-stream at as high a degree as possible by the use of tuberculin; sixth, it is interesting to note that the patient is able to say, based on her subjective symptoms of well being, or the opposite, following a dose of vaccine, as to whether the dose as given is increased or diminished. It has been found in every instance in which the dosage has reached 1-2,000 mgm. the patient does not feel as well for three or four days after inoculation. It has been found that a dosage of from 1-8,000 to 1-5,000 mgm. (bacillary substance) is the most satisfactory with which to maintain the present excellent condition. There has been in the treatment of this case at no time any suspicion of subjective symptoms following either the colon vaccine or the tuberculin.

This case illustrates sufficiently well the rôle of tuberculin, namely, of increasing the antibacterial power of the blood stream, to the end of rendering the immunizing mechanism more efficient in coping with the residual tuberculous process, after the major portion has been removed.

VESICAL TUBERCULOSIS WITHOUT EVIDENT RENAL INVOLVEMENT.

There may occur, according to Walker (*loc. cit.*) a considerable number of cases of tuberculous cystitis, unaccompanied by demonstrable renal involvement. Of 42 cases, he found 10 in which the disease was apparently confined to bladder, and 32 in which foci were found in other parts of the urogenital system. In 23 of these 32, the other involvement was in the genital system.

When, as a result of the application of usual methods of diagnosis it is concluded that the bladder is the chief seat of involvement, we have a condition unsuitable for surgical treatment and unsatisfactory with other usual methods.

We have to deal with a tuberculous infection of a mucous membrane, ulcerated and indurated. Such lesions are definitely known to be amenable to tuberculin.

Again quoting Walker (*loc. cit.*):

"In such cases best results may be obtained from tuberculin treatment." He states that sometimes after two or three injections the patient will report improvement. Less often the symptoms persist in increased or lessened severity, and improvement is only obtained after many months of treatment. The patient first experiences increased vigor, pain diminishes and disappears, and calls to micturition become less troublesome. From a frequency of fifteen minutes during the day and incontinence at night, improvement to two hours through the day and once or twice at night may be obtained in several months. Hematuria gradually ceases. The urine remains for a long time without change, but may eventually become clear, and the urinary pigment, which was deficient, increased. The patient put on weight.

He selects the following case from a few in which the tuberculous process has apparently been arrested:

Man, thirty-one, in July, 1903, had hematuria and hemoptosis. For four years cystitis, symptoms had increased gradually. Cystoscope showed ulceration left side of bladder. Groups of fine tubercles found. Four months treated with drugs. Symptoms the same. Steadily lost weight. Tuberculin begun November, 1903, 1-250 mgm., repeated every two weeks. January, 1904, urine unchanged. He ceased to lose flesh, held his urine four hours during the day, rose once at night. Much stronger, and had regained former figure. Cystoscope showed groups of tubercles, but less ulceration. Hemoptosis in March, 1904, and about weekly during the early part of the year. He began to gain flesh and appearance showed improvement. In 1904 burst of hemoptosis and hematuria. September, 1904, to January, 1905, had gained one stone and a half in weight. Cystoscope, June, 1905, showed few fine tubercles; ulceration had healed. September, 1905, no pain or hematuria. Urinated three or four times a day, not at all at night. Urine still hazy, trace of pus. January, 1906, injection reduced to 1-1,000 mgm. for three weeks. Blood appeared in urine and was present some weeks. It disappeared and the urine gradually cleared, with increased doses of tuberculin. Urine became absolutely clear and remained so for several months. July, 1907, attack of cystitis. Urine cloudy, no tubercle bacilli found, numerous staphylococci. Recovered from this attack of staphylococcus cystitis and feels well.

Jones reports the cases of tuberculous cystitis treated in Wright's clinic as follows:

Two cases cured; 4 much better; 8 better, meaning either some relief from pain or frequency of micturition. One case was no better, 1 worse and 1 unknown. There were relapses in 5 cases. In 13 cases there was secondary colon infection. In 10 of the successful cases, initial dose was less than 1-15,000, but often 1-25,000. After a time it was raised gradually to 1-4,000. Serious results may follow large initial doses. Treatment of successful cases averaged one year two months. Five or six were treated six months or less.

The writer has treated a case of genito-urinary tuberculosis which in its early history furnishes an excellent illustration of the course of an untreated case of tuberculous bladder, apparently unassociated with renal disease.

In early October, 1908, F. G., male, about twenty-eight years old, was referred for treatment. For ten years he had suffered from frequent micturition, generally every two or three hours. For three or four years had passed a little blood once or twice each year. At times there was considerable pain and burning on micturition, but this was not constant. Four years before the above date the symptoms of cystitis became marked, and when blood appeared he was referred to a surgeon for observation. Cystoscopy was at the time performed by J. H. Cunningham, Jr., who found several ulcerated areas in the mucous membrane, and made a positive diagnosis of tuberculosis. During the following four years he occasionally passed blood, had some pain on micturition. Frequency every two or three hours; once or twice at night. Urine generally not cloudy. His general health continued to be fairly good, although untreated. In October, 1908, he developed a swollen right testicle, which was, when the writer saw it, the size of a clenched fist. It had become swollen in a few days; was only slightly tender. His physician believed it to be due to the gonococcus, but there was no history of exposure or clinical evidence of the disease. The Von Pirquet cutaneous reaction was intensely positive. In a short time the tissues broke down, fluctuation was made out and considerable thick pus was aspirated. No pyogenic organisms were present. A guinea pig inoculated, killed after four weeks, showed tubercle bacilli in the mesenteric glands, inguinal glands, and tubercles were found studding the peritoneum.

The sequence of events in this case, and the observations, furnish clean-cut evidence of a tuberculous cystitis extending over a period of years and final extension to the testicle.

It indicates that, in an apparently healthy individual, tuberculosis may exist in the bladder for a long time, and illustrates the tendency of bladder tuberculosis to extend to other organs of the genital system. It is particularly interesting, because of the sequence of events in the same case following use of tuberculin for a considerable time. The treatment of this case will be considered under the next heading.

VESICAL TUBERCULOSIS ASSOCIATED WITH TUBERCULOSIS OF THE GENITAL SYSTEM.

In 23 cases cited by Walker (*loc. cit.*) tuberculosis was found to be coexistent in the bladder and in some of the genital organs. This association is very commonly met with.

He states that his patients steadily lost ground under various local and general treatment, and that he considered them eminently suited for tuberculin treatment, that in none of them was he able to bring about a cure, though he treated them over long periods. In most cases a considerable amelioration of symptoms was obtained. The distressing, frequent and urgent micturition is sometimes diminished to a remarkable degree.

One illustrative case, a man, thirty-eight, when seen, had symptoms of cystitis for eighteen months. Left seminal vesicle was hard and in the left lobe of the prostate was a large hard nodule. Tubercle bacilli found in the urine. Cystoscope showed a cystitis without definite tubercles. During six months tuberculin was given. Dosage, 1-2,000 to 1-800 mgm. He gained weight; there was no blood in his urine since the early part of the treatment. Micturition less frequent.

A second case for four months urinated every ten minutes and was incontinent at night. Urine thick and milky, prostate and seminal vesicle affected. After four months there was a gain of weight, lessened pain, urination every one and a half hours during the day; every two hours at night. After twenty-one months' treatment urination was every three hours, and twice at night, still milky. At the end of twenty-eight months' treatment the urine was clear, frequency every three hours in the day time, once at night.

The case "F. G." will be here continued as one of tuberculous cystitis with secondary testicular involvement.

Beginning Oct. 7, 1908, Tuberculin R. was injected once a week, initial dosage 1-20,000 mgm. (bacillary substance), the second 1-15,000 mgm., the third 1-10,000 mgm., the latter repeated weekly until Dec. 22, when it was increased slightly to 1-8,000 mgm. After the pus was aspirated from the testicle, a discharging sinus continued to discharge until the last of December. The testicle gradually lessened in size and the epididymis could be felt as a somewhat enlarged, hard mass. After the first four doses of tuberculin, micturition became less frequent (for several years it had averaged every two or three hours). On Dec. 22, 1908, after about three months' treatment, the patient stated that for the past week he had several times held his urine seven hours without much discomfort, and had not been up at night to micturate for some time. June 15, 1909, the dosage had reached 1-2,000 mgm. T. B. Urination every four or five hours and not at all at night. Aug. 3, Tuberculin B. E. was substituted for Tuberculin R. inasmuch as results in other cases appeared to be superior than those obtained by the use of Tuberculin R. Initial dose 1-20,000 mgm. Dec. 24, 1909, dosage had reached 1-1,000 mgm. B. E. and the last dose, March 4, was 1-800 mgm.

The testicle is now of practically normal size, the epididymis hard, but smaller than at first, micturition three or four times a day, never at night; pain after micturition, as experienced at first, has almost disappeared; no blood in the urine since treatment was begun; weight about as usual; general condition excellent; subjectively and objectively perfectly well; has been able to attend to business from the start of treatment as he had previously, but with less discomfort. He has received no local or general treatment other than tuberculin and advice as to hygiene.

There has been no suspicion of constitutional or focal reaction following injection of vaccine.

This case is of interest in the matter of diagnosis. The finding of tuberculous ulceration in the bladder, in 1904, indicates that bladder symptoms, extending over from five to ten years, were within reasonable probability due to a condition of tuberculous cystitis; testicular involvement, which occurred four years after ulcerations were found, and was proved to be tuberculous by animal inoculation, confirms the accuracy of Dr. Cunningham's cystoscopic diagnosis.

The case is further valuable, as indicating the efficiency of tuberculin so far as indications may be obtained from study of any one case. Symptoms had gradually gotten worse over a long period previous to the beginning of tuberculin treatment, and involvement of testicle came as evidence of unfavorable progression of the tuberculous process. The improvement associated with the exhibition of tuberculin may not only be taken as evidence of its efficiency in cystitis, but also in an early tuberculous process in the epididymis.

The outcome of the case also shows that tuberculin may be given successfully without the production of any symptoms of intolerance of either a general or a local nature.

The question of when to stop tuberculin treatment can only be determined by the method of trial and error. The writer proposes to inoculate a guinea pig with the centrifugalized sediment of the urine. If bacilli are to be found in the urine, the treatment will be continued; if not found, tuberculin will be stopped for a month or two and the patient kept under careful observation. Tuberculin will be started again if increased frequency of micturition, pain, or other symptoms of cystitis develop.

TUBERCULOSIS OF THE GENITAL SYSTEM.

The chief danger of tuberculous infection of the genital system is that it may infect the bladder. Walker (*loc. cit.*) considers the onset of cystitis to indicate extirpation, if possible, of the organ involved, but otherwise does not make use of extensive operative procedures, this because of the tendency of these lesions to contract and become walled off as a result of the benefit of tuberculin and general hygienic measures.

He reports a case of tuberculous epididymitis, prostatitis and vesiculitis, in which decided improvement took place after four years' treatment. The lesion in the epididymis in this case was of nineteen years' duration.

Jones (*loc. cit.*) reports the following cases of tuberculous testicle treated in Wright's clinic; 3 cases were cured, 2 "much better," 2 "better," and 2 doubtful as to the result.

Jones sums up 34 cases of genito-urinary tuberculosis treated with tuberculin in Wright's clinic as follows: The results would indicate that great improvement may be obtained in 3 out of 7 cases, and slight improvement in 2 more cases; treatment may last a year or more. There were secondary infections in one half the cases.

ACUTE PANCREATITIS, WITH THE REPORT OF TWO CASES.*

BY PHILEMON E. TRUESDALE, M.D., FALL RIVER, MASS.

ACUTE pancreatitis is an appropriate subject to present for your discussion at this time, for it is about twenty years since the notable contributions of Dr. Reginald H. Fitz[1] marked an epoch in our knowledge of this disease. The Middleton Goldsmith lecture was delivered by him before the New York Pathological Society in 1889. In this essay there was outlined a more definite and precise symptomatology than had hitherto been known. The classification of the disease by Dr. Fitz was based upon a comprehensive study of the terminal pathology, and was fundamental to the intelligent interpretation of diseased processes in the living subject. His

* Read before The Massachusetts Medical Society, June 7, 1910.

accurate deductions are still quoted by the authors of our modern textbooks.

At that time the origin of the disease was attributed to the extension of a gastro-duodenal inflammation along the pancreatic duct. Some investigators have maintained the theory of chemical and autodigestive changes. Of these, Truhart [2] reported 74 cases of acute pancreatitis, in only 14 of which were micro-organisms demonstrated. That, however, would not eliminate their presence as a cause in a much larger number. The frequent accompaniment of gallstones and their septic influences have been pointed out by Fitz,[3] Opie,[4] Flexner,[5] Robson,[6] and others, who have proved the association of these infections from the biliary tract. Opie [7] discovered this relationship at an autopsy of a case operated by Bloodgood. A gallstone, the size of a pea, was found occluding the ampulla of Vater, thus forming a continuous passage through which the bile traveled from the common duct directly into the pancreatic duct. To this interesting discovery he added seven others, and inferred that in many cases the stone might be temporarily lodged long enough to allow damage to the pancreas and then escape, leaving no other evidence of its presence.

The close anatomical relationship of the pancreatic duct and common bile duct is an important factor in the associated pathology. In a large percentage of cases the opening of the common bile duct is surrounded by pancreatic tissue.

Egdahl,[8] in an analysis of 108 cases, says that about 42% of the cases of acute pancreatitis are associated with gallstones, and considers them the most common single cause. Although the consensus of opinion is in favor of infectious agents from the intestinal tube and bile ducts, in 10% of Egdahl's cases the presence of mumps was an associated and causative factor. This is evidence that metastatic infections, either through the blood or lymphatic stream, enter into the etiology.

The hemorrhagic phenomenon which is present in the fulminating cases remains unsolved. When death occurs early the extravasation of blood seems to dominate the whole process. The theory that arteriosclerosis produces this dyscrasia has been disproved. Mr. Robson [6] has suggested that the hemorrhage may depend upon the presence of glycerine. Others have attributed the hemorrhage to the action of the pancreatic juices. Williams [9] found that in Kaiserling preparations from specimens of the acute hemorrhagic pancreas the colors did not materialize and thought possibly that the action of the pancreatic juices had something to do with this result.

When these hemorrhages occur, the disintegration of the substance of the gland ensues, and infection promptly converts the process into an acute fulminating inflammation.

The frequency with which the abdomen has been explored in recent years has made possible the recognition of the less fulminating and yet acute inflammations of the pancreas. The presence of fat necrosis is considered the pathognomonic sign. This lesion results from the escape of pancreatic ferments into fat tissue, splitting the fats into fatty acid and glycerine. Langerhans first produced this change by injecting into rabbits and dogs an infusion, made by grinding up the pancreas of a freshly killed rabbit with finely splintered glass, and succeeded in producing a small opaque focus at the site of injection which had the histological characters of fat necrosis. He consequently concluded that it was possible to produce fat necrosis by the action of fresh pancreatic juice upon living fat tissue. Balzer,[10] in 1879, first recognized the association of fat necrosis in acute pancreatitis.

Opie,[11] in his experiments, succeeded in reproducing the more widely spread condition of fat necrosis observed in man, and showed that the same cause is responsible for it as for the local lesions. Flexner [12] and Oser [13] found that injections of dilute acids, dilute alkalies, artificial gastric juice, turpentine or suspensions of bacteria, while causing more or less serious injury to the parenchyma, were liable to be accompanied by necrotic changes in the pancreatic and abdominal fat. Clinically, its recognition is of great importance, since its presence in practically all cases is taken to indicate a severe inflammatory lesion of the pancreas. It was formerly interpreted as a fatal sign, but we know to-day that its presence does not necessarily indicate a lethal termination. Truhart disproved the old theory by collecting ten cases in which fat necrosis was present, and yet an immediately fatal issue did not result.

The changes which occur in the gland itself in acute hemorrhagic pancreatitis are usually rapid and destructive, involving the entire parenchyma of the gland. As a result we have degeneration of the entire glandular elements. The islands of Langerhans are less readily destroyed than the secreting cells of the acini.

The following two cases have occurred in my practice:

Case I. S. C., female, age fifty-three, single. Seen in consultation with Dr. A. C. Peckham, Dec. 3, 1907. She had always been well except for an attack of acute indigestion in 1904. Since this attack she complained of habitual constipation, but her digestion was not a source of discomfort. Dec. 1, 1907, following a period of constipation of three days' duration, she developed severe acute symptoms. Epigastric pain radiating to both sides, vomiting of mucus and bile; the pain with a sensation of fullness in the epigastrium continued except when temporarily relieved by hypodermic injection of morphia. She was admitted to the hospital on Dec. 4. Temperature, 100; pulse, 100. The patient was obese and had a slight degree of jaundice. Her abdomen was distended and tympanitic. There was tenderness over the upper half, with spasm of the right rectus muscle. Urine negative. Diagnosis, gallstones.

Upon opening the peritoneal cavity through a right rectus incision the omentum was found adherent around the gall bladder and pylorus. The duodenum was engorged. Scattered over the omentum, duodenum and gall bladder were small, round, opaque areas. The gall bladder was distended—thickened and not collapsible. The head of the pancreas was considerably enlarged. The gall bladder, which contained inspissated bile and a deposit of very fine granular material upon the mucous membrane, was drained. A small piece of omentum and a portion of the fundus of the gall bladder,

upon which were several of the small opaque areas, were removed for histologic examination. These showed a leucocyte infiltration surrounding small areas of fat necrosis. The patient recovered.

CASE II. My second case was of the acute fulminating type and characterized by the group of symptoms detailed by Dr. Fitz in 1889: "Sudden, severe, often intense epigastric pain without obvious cause, in most cases followed by nausea, vomiting, sensitiveness and tympanitic swelling of the epigastrium. There is prostration, often extreme, frequent collapse, low fever, and a feeble pulse."

On Oct. 26, 1907, Dr. George G. Parlow was called to see Mrs. L. F., aged twenty-six years, housewife, native born. Well up to the time of her marriage, when she complained of a muco-purulent discharge from the vagina, associated with frequent and painful micturition. Jan. 25, 1907, was delivered in normal labor of a poorly developed fetus at about the eighth month of gestation. She developed a bilateral pyosalpinx and pelvic abscess during her convalescence. On March 1, 1907, both fallopian tubes and the left ovary were removed. Drainage was employed for a large ovarian abscess which had ruptured during its enucleation. Discharged from the hospital, March 30, weight 174 lb. Her general health improved, and except for obstinate constipation, she was symptomatically well up to the morning of the attack now to be described. Her weight some days before was 230 lb.

On Oct. 26, while in her yard, following mild but sudden exertion, she was seized with agonizing pain in the epigastrium. She fell upon the ground and remained there for several minutes, then managed to walk into the house. Hot drinks and hot applications proved ineffectual for relief. She vomited an ordinary basin full of dark fluid material. Dr. Parlow's first observation was made a few hours after the onset of her attack. She was in a state of collapse, with a rapid, feeble pulse and subnormal temperature, perspiring freely, and indicated the epigastrium as the location of her pain. Cardiac stimulants were administered by hypodermic injection, and a gradual recovery ensued. The pain was most severe in the epigastrium and radiated toward the left groin, and was aggravated by turning upon the same side. Tenderness over the abdomen was general. An enema was given without result. The pain was relieved only by hypodermic use of morphia. On the following morning the pulse at 130 had improved in quality. The temperature was 101° F. She described the discomfort in the epigastrium as a feeling of intense weight, unremitting and radiating to the back. There was no vomiting after the first day. An ice-bag upon the abdomen gave the most comfort. On Oct. 30 there was noticed a slight degree of jaundice, the urine was a deep red, and a small stool by enema was of light yellow color. During the next few days she remained in a precarious state, the pulse varying between 120 and 130, the temperature from 99.5° to 102°. Flatulence was a troublesome symptom, and the abdominal discomfort thereby made extreme was relieved by enemas.

On Nov. 4 I saw the patient in consultation with Drs. Parlow and Curry. She complained of a constant dull aching pain across the upper abdomen, with occasional paroxysms induced by the formation of gases in the stomach and intestines. Her face wore an expression of exhaustion and pain. Tongue was dry. Sclera had a yellowish tint. The abdomen was distended, tympanitic and tender everywhere, especially in the zone above the umbilicus, where there was an indurated mass the margin of which could not be well defined. The temperature was 101.5° F.; pulse, 130; respirations, 36. I had palpated her gall bladder at a previous operation and had felt no stones. Acute cholecystitis with perforation and abscess was considered, as well as abscess from perforation of the stomach, duodenum or tranverse colon. In view of the absence of earlier symptoms pointing to the biliary or intestinal tract, together with the suddenness and severity of onset, slight jaundice and the presence of a tumor in the epigastrium plus peritonitis, the diagnosis of acute pancreatitis was ventured. The patient appeared to be on the border line, her condition hardly justifying surgical interference.

White blood count, 35,000; polymorphonuclears, 83%; lymphocytes, 11%; large mononuclears, 5%; transitional, 1%.

Operation on Nov. 6 at the patient's home. During the previous twenty-four hours there had been eight bowel movements, moderate amount, liquid and pale in color.

The abdomen was opened in the mid line above the umbilicus. The subcutaneous fat was quite yellow. A sero-sanguineous fluid escaped from the peritoneal cavity. Beneath the parietal and visceral peritoneum were disseminated areas of fat necrosis. These were numerous and conglomerate in the immediate vicinity of the pancreas. The gall bladder was distended. No stones were felt. The pancreas was much enlarged, and presented a dark mottled appearance through the gastro-colic omentum, to which it had become attached. An incision was made through the peritoneal cover, and the finger passed into the body of the pancreas, the substance of which was very friable and bled freely. In spite of the hemorrhage, wide deep openings were made into the gland. No pus cavities were opened. Fragments of the necrotic pancreas and the omentum were removed for examination. Tubes of Loeffler's blood serum were inoculated from the necrotic tissue; these remained sterile. Split rubber tubes enclosing gauze were used for drainage and the wound dressed.

The operation was of short duration, and there was no apparent shock. The pathological findings were as follows: The specimen consists of a small piece of omentum and some separate bits of a very friable hemorrhagic tissue. The specimen from the omentum has several yellowish-white, greasy spots, varying in size from ¼ to ½ cm. in diameter.

Microscopical examination. — Sections of the omentum show numerous areas of fat necrosis. Sections from the hemorrhagic tissue show much free blood and cell detritus surrounding definite areas of necrosis. In one spot there is connective tissue, marking off what apparently corresponds to a gland lobule. Within this lobule are the faint outlines of gland acini; some of them are outlined in blood. No living cells, but much nuclear detritus is seen throughout the section.

Diagnosis. — Acute hemorrhagic pancreatitis.

The convalescence was eventful. The temperature and pulse gradually approached normal for the first week. The discharge from the wound was copious, mixed with blood for several days, followed by the thin secretion from the gland, containing pus. This discharge subsequently became very irritating, causing a dermatitis over a large area. A paste of castor oil and bismuth proved to be very effective in relieving the consequent discomfort and limiting the extent of the excoriated surface.

On the ninth, tenth and eleventh days the discharge diminished perceptibly, and the temperature rose to 103°, pulse 140 and respirations 40. The sinus was enlarged by the introduction of the finger, after which free drainage was re-established. For the subsequent week the patient's condition was not encouraging. There was an irregular elevated temperature, with pulse between 130 and 140. On the twentieth day after operation I removed a sloughing mass which presented

at the opening of the sinus. It measured 15 cm. by 3 cm., and was composed of a mass of necrotic tissue surrounding a central duct which coursed its entire length. (See Fig., Case II.)

On Nov. 27 patient had a chill, followed by phlebitis in the right leg. Again there followed a wide variation of temperature with rapid pulse. There was but little hope for her recovery at this stage. A culture was taken from the discharging sinus. An autogenous vaccine was prepared by Dr. George P. Sanborn from the growth of colon bacilli. This was administered at first in doses of ten millions on Dec. 7 and 8, twenty millions on Dec. 10 and 11, thirty millions on Dec. 14, 17 and 21. There followed a gradual approach to normal of temperature, pulse and respiration. Sugar had appeared in the urine, but was not estimated quantitatively until Nov. 28, when there was found 5.2% with the polariscope, and Lohnstein tube specific gravity was 1.026. No albumen. Twenty-four-hour amount, 90 oz. On Dec. 2 the amount of sugar diminished to 0.7% by Lohnstein tube; on Dec. 5, 0.43%, and it was found absent for the first time on Dec. 9 by Mylander's solution, and did not reappear. The twenty-four-hour amount varied from 72 oz. to 90 oz., and the specific gravity from 1.005 to 1.011. Four-ounce starches were added to the diet on Dec. 16 and continued for one week, when a mixed diet was allowed. The stools during this period were normal, well digested and contained no starches or fats. Fat globules were observed on Nov. 10 and in several liquid discharges on later dates.

On May 2, 1910, this patient was found to be in good general health. Her weight had returned to 205 lb. She complained of epigastric distress from one to two hours after meals, especially if she had eaten meat and potatoes. Her bowels alternated between constipation and diarrhea. Examinations of the urine and feces were made by Dr. Herbert as follows:

Urine: specific gravity 1.028, acid, no albumen, no sugar with Mylander's reagent. Urea with a Doremus test, 0.018. Stools showed undigested muscle fiber. No starches or fats.

June 3 test breakfast was administered, the examination of which showed an entire absence of free and combined hydrochloric acid. Also an absence of chlorides, which would account for undigested muscle fiber.

DIAGNOSIS.

The diagnosis of acute pancreatitis usually is made after exploratory incision. The cases of moderate severity are the most difficult to recognize. Frequently associated with an acute cholecystitis or cholangitis, it remains difficult to determine the source from which the symptoms originate. In Case I the pain was at first located in the epigastrium, later becoming general, with occasional paroxysms, and it returned after the influence of the morphia had worn off. With the appearance of jaundice these cases simulate a suppurative cholangitis. The head of the pancreas is early involved, and, although the pain is referred to the epigastrium, it radiates over the abdomen rather than to the subscapular region. Tenderness and muscular spasm are usually more pronounced in the right upper quadrant. In the presence of such symptoms pancreatic infection can only be suspected.

The Cammidge [14] reaction which was first described in 1904 has received recognition as a diagnostic test by many writers, including Robson,[15] Moynihan,[16] Ochsner,[17] and others. In the application of this test one should be reasonably skeptical. It is quite likely to be found positive when so desired, and vice versa.

In sixty-two cases of pancreatitis, Pilcher,[18] of Rochester, Minn., found the urinary reaction positive in 82%. Positive reactions were obtained in all the so-called subacute cases. He concludes that a typically positive reaction with a negative control is almost pathognomonic of pancreatitis.

The errors in Pilcher's investigations were pointed out by Dr. Wilson,[19] pathologist at the same hospital, in a paper read at the Triennial Congress at Washington, one month ago. His tests were carried out by taking the urine from patients whose histories were not sent to the laboratory. He obtained the reaction in cases which were not found at operation to have pancreatitis, and he failed to obtain the reaction in others in which the presence of the disease was demonstrated at operation.

He went further and obtained a positive reaction in the urine of young healthy adults temporarily overfed. Dr. Wilson, therefore, concluded that the presence of this reaction was related to the changes of metabolism, and that its value as a diagnostic agent in pancreatitis was open to doubt.

The acute hemorrhagic cases are confounded at first with intestinal obstruction, and perforating ulcer of the stomach or intestine, phlegmonous cholecystitis or ruptured gall bladder and ptomaine poisoning. Although intestinal obstruction does occur at the same time, it is limited to that portion above the jejunum. The patient may pass flatus with repeated enemas. The distention is less marked in pancreatitis than in intestinal obstruction. Vomiting in the latter condition is persistent, while in acute pancreatitis it may subside early. In cases of a perforating ulcer an ulcer history may be obtained. If ruptured gall bladder is suspected, previous evidence of trouble may be found. In ptomaine poisoning there is diarrhea from the beginning.

In acute pancreatitis the onset of the attack which may follow a period of constipation is sudden, severe and frequently followed by collapse. Vomiting occurs early. If death does not supervene, the process becomes circumscribed, jaundice appears, the stools become bulky and contain fat. Ochsner [20] and Opie [21] have observed cyanosis as a symptom.

Elliot [22] mentions the fact that in acute pancreatitis a tympanitic note on percussion is obtained over the tumor by the location of the gland behind the duodenum and pyloric end of the stomach. The pancreas may become so large, however, as to appear in contact with the anterior abdominal wall and collapse the duodenum.

TREATMENT.

There are mild cases which undoubtedly clear up without treatment. When the disease is of moderate severity and associated with cholecys-

titis and cholangitis, drainage of the bile passages is indicated.

In acute hemorrhagic pancreatitis the situation differs somewhat from that found at the beginning of an acute fulminating process in the appendix, gall bladder or pelvis. In the latter diseases operation in the first twenty-four hours usually finds the patient in as favorable a condition as he will be, while in acute hemorrhagic pancreatitis, the degree of shock which accompanies the onset of the disease must be added to the risk of surgery.

Mayo Robson [23] advocates operation before the period of collapse has passed off, since he says that this may be dependent upon septic absorption.

Mikulicz [24] believes that we should not in general allow the severe symptoms to pass and delay the operation until the formation of an abscess. Nevertheless, of the cases which he collected, only 9 out of 46 operated upon in the acute stage recovered, while 18 out of 35 recovered when the operation was performed in the later stage. However, he points out the unsatisfactory side to such statistics, inasmuch as most cases were operated upon under mistaken diagnosis of perforative peritonitis or intestinal obstruction, and the abdomen thoroughly explored for the suspected perforation or occlusion. The post-mortem examination in these cases first demonstrated the true condition. It is obvious that such "irrationally conducted" proceedings in the presence of an already existing condition of shock must result in a high mortality.

It is probable that many of the surgical deaths incurred by operations undertaken in the first twenty-four hours would be medical deaths if let alone, yet an operation if not carefully and expeditiously executed can, at the outset, remove the only chance a patient may have for recovery. Every death from acute pancreatitis in the first twenty-four hours is not necessarily from surgical neglect.

When an acute process assumes a severe hemorrhagic character, as the result of a dyscrasia similar to that which occurs in a pure pancreatic apoplexy, but little hope can be entertained from operative interference. A patient presenting the symptoms of shock at the onset of this disease, when the diagnosis can be made, should be treated by the use of hot saline infusions first and surgery later. When a differential diagnosis cannot be made, and the degree of shock is not too severe, immediate exploratory laparotomy would seem to be indicated. Whether the condition disclosed is a perforation of the stomach, intestine or gall bladder, or an acute pancreatitis, a short, well-executed operation will offer the most hope.

Dr. Fitz,[25] in his original monograph, dismissed the treatment in the following paragraph: "It is evident that all treatment at the outset can be nothing but palliative. With the formation of pus in the omental cavity comes the opportunity for the surgeon. The possibility of the successful removal of the pancreas is suggested by the healthy condition of the patient seventeen years after he had discharged this organ from his bowels." This is the attitude of many conservative surgeons of to-day.

The second case reported above is an example of many others in literature showing the tendency of the destructive process to become circumscribed and the resistance which may be manifested in a case the onset of which was quite severe.

The operation upon this patient, although performed at a much later date in the course of the disease than would ordinarily be selected, probably presented a more favorable outlook than if it had been done in the first twenty-four hours.

Nevertheless, appreciating the danger of gangrene, the formation of a phlegmon in the loose tissues of the retroperitoneal region rich in lymphatics, and of general sepsis, one would not wisely delay operation after the pulse had recovered a good quality.

DISCUSSION.

Dr. David D. Scannell, of Boston: I think I can best crystallize my remarks on the subject by presenting a case of acute hemorrhagic pancreatitis actually operated on July 1, 1909 (the patient is present in person).

George F. S., fifty-five, wood-turner. Boston City Hospital, July 1, 1909. Family history negative. Previous history also negative from the point of view of symptoms referable to the condition for which he was operated.

Present illness. — Three days ago, patient was seized with acute stabbing pains in his upper abdomen; to use his own expression, "he retired in apparently good health at 9.30 P.M. and awoke at 11.30 P.M. with sharp pains like knife thrusts through the stomach, followed by vomiting until 7.45 the next morning. No symptoms of collapse. These pains were associated with more or less gradual distention of the abdomen and marked constipation. After twenty-four hours the vomiting ceased, and patient found his greatest discomfort in dull epigastric pain and the abdominal distention. After twenty-four hours in bed, the patient took a train to Boston, a six hours' journey, sitting up the whole distance in an ordinary passenger car during the whole of his journey. His suffering was intense, and his color and expression so bad that he was a source of much anxiety to his fellow-passengers. From the time of his arrival in Boston until his admission to the Boston City Hospital (seventy-two hours from the beginning of the attack), his abdominal distress was intense.

Physical examination at the time of entrance. — Patient in a state of collapse and suffering intensely;

face pinched, slightly cyanotic and anxious; nose cold; tongue heavily coated; slight jaundice in both sclera, though no cutaneous jaundice could be made out; pulse 128 and of wretched quality; temperature 99.8°.

Abdomen markedly distended and spastic throughout, the greatest spasm being in the upper half of the abdomen and here most marked just to the right of the middle line. While tender all over, the abdomen was most tender in the epigastrium and right hypochondrium, the distention and spasm making definite palpation quite out of the question. There was dullness in both flanks and tympany above; rectal examination was negative.

Diagnosis. — The history and the physical examination seemed to make the diagnosis of acute hemorrhagic pancreatitis the most probable one, though an acute gall bladder, with or without perforation, or a perforated gastric or duodenal ulcer, were kept in mind.

Operation. — High right rectus incision. Immediately on opening the abdominal cavity, a moderate amount of sero-sanguinolent fluid escaped; the intestines were everywhere distended; there was no evidence of fat necrosis. Directly under the incision, and occupying the anatomical site of the head of the pancreas, was a mass of adhesions, roughly comparable to the size of a clenched fist; this mass continued to extend across the abdomen, about the direction of the pancreas, though less large than under the wound. Before exploring this mass, the stomach was inspected and showed no perforation; the duodenum was covered over by the mass, and, therefore, was not to be scrutinized; the gall bladder was moderately distended, but to quick palpation presented no abnormality; no stones were to be felt; the general peritoneal cavity was walled off with strips of gauze and the mass explored with the finger; immediately there set up a most brisk hemorrhage, coming from no particular vessel, but from the whole mass; the finger, without difficulty, went down through the swollen area to what was unquestionably the head of the pancreas; the patient's condition, wretched to start with, became distinctly and acutely worse, and it was deemed wisest to terminate operative procedure as rapidly as might be; gauze packing in considerable amounts was pushed down to virtually the patient's back bone, and the hemorrhage fairly controlled. In view of a possible association of a chronic gall bladder as the cause of the pancreatic lesion, it seemed wisest to drain the gall bladder, which was rapidly and easily done, rubber drainage being used. The abdominal wound was closed for the most part and shock treatment and slow saline by rectum were instituted.

Recovery was astonishingly rapid. The original packing was removed gradually, so that it was entirely out by the fifth or sixth day. There was almost immediately evidence of slight digestion of the wound from the escape of pancreatic juice. The gall bladder drained efficiently, and all drains were out on about the twelfth day. After the operation, practically no pain whatever was complained of. Three weeks from the day of operation the patient was discharged well.

Four weeks later, the patient was readmitted, with severe pain in his right hypochondrium over the site of the incision, associated with nausea and vomiting. At this time, physical examination showed extreme tenderness over the old scar and a localized swelling about the site of his gall bladder. Under ether, the previous scar was opened up with an escape of about one-half pint of thin bile. This was drained, and the patient did well for fifteen days, during which interval he drained bile freely. His general condition steadily became worse, with a complete loss of appetite and a distinct loss in weight. During the latter period of this interval, more or less definite pain was complained of below and to the right of the umbilicus, with the development at this site of definite spasm, tenderness and swelling. A third operation was done and a large amount of straw-colored, flaky fluid evacuated; there was no frank pus. The omentum and serous covering of intestines showed evidences of fat necrosis. Drainage was established and for some days little hope was entertained of the man's recovery. For three weeks after this last operation the discharge from both incisions was most free. At the end of that time the discharge stopped and the patient rapidly regained his health, and within a month of the last operation was discharged well. Since that time there has been a steady and progressive gain in every respect, with entire absence of digestive disturbances, increase of weight and general betterment.

Dr. Tobr Wagner Harmer, of Boston: I was interested to hear what Dr. Truesdale said of the Cammidge reaction. I think, if any one has worked conscientiously with this test in the laboratory with a clinical knowledge of the cases, he can spell out in a very few words "the Cammidge reaction is dead." It is not a specific test for pancreatic disease. Dr. Boos and I have been interested in working on this subject, and have performed a large number of tests. We have been careful to exclude any material containing sugars, and with but a few exceptions have selected only those cases in which pancreatic involvement seemed unlikely. Every case with a white count over 17,000 showed a positive Cammidge reaction, regardless of the clinical condition, and regardless of the type of leucocytosis, neutrophilic, basophilic or myelocytic. We obtained autopsies of four cases, and in each the pancreas was normal. Again last year Dr. Boos obtained a negative test in a case of Dr. Balch's with acute pancreatitis. You will find a number of instances reported in the literature (Bushnell, Gruner, Schroeder, Ransohoff, Kinnicutt, Lyle) in which the test was negative and the pancreas diseased.

Dr. Daniel Fiske Jones, of Boston: In regard to diagnosis, I do not hear much said about the differential diagnosis between pancreatitis and intestinal obstruction. The first lot of cases I saw were all diagnosed as acute intestinal obstruction. This mistake is not so frequently made at present. Then in regard to operation, it seems to me it ought to be emphasized a little more that practically the only possible treatment for these cases is early operation — and by operation I do not mean simply an exploratory laparotomy, but a thorough opening up of the capsule of the pancreas itself. This area should be packed with gauze to prevent escape of pancreatic secretion into the general abdominal cavity, and to give drainage. The operation to be of value must be early, and the gland freely opened up to relieve tension before extensive destruction of the gland takes place.

Dr. J. C. Munro, of Boston: There are one or two points which I should think should be emphasized. It is possible to get well without opening up the pancreas. I have seen a number of such cases both at the hospital and one or two in my own private practice where simply opening the abdomen apparently cured the patient. There is no doubt that in the acute cases there is nothing but surgery that ought to be considered. I have operated on a dozen or more, and don't think that in most of them the question of intestinal obstruction came in at all. The thing that has aided me in clearing up a diagnosis of a case before operation is the presence of a high pulse and a rather low temperature, the fact that the pain is intense, the fact that all these patients have a slight jaundice which is not the jaundice of gallstones, but is the jaundice that goes with the pancreatic infection of the gall bladder.

We see it in cases of acute pancreatitis. In the first three or four hours the pain and spasm is all in the upper part of the abdomen. It is, I think, rather characteristic. I think the outlook is not so black as the books would have us believe if these cases are operated on before the patients are *in extremis*. I think that drainage of the pancreas is sufficient, as where there is not acute hemorrhage we do not use much gauze packing; we use just a strip or two.

DR. F. B. LUND, of Boston: Some years ago I reported six cases of this disease, and in these cases, as in my subsequent experience, I have been much impressed with the difficulty of making a diagnosis between acute pancreatitis and perforation of the stomach or gall bladder. The rise of temperature, tenderness, spasm and absence of constipation have served to render a diagnosis of intestinal obstruction improbable. The picture of acute pancreatitis is very much like the picture of acute perforations, especially of the gall bladder, for the reason that they are usually preceded by a history of gallstones. The percentage of cures, owing to the position of the pancreas, virulence of the infection and the difficulties of drainage, will always be great, but without drainage, and judicious drainage, all the cases of gangrenous pancreatitis certainly must die. It is astonishing how much of the pancreas can slough and at the same time leave behind enough pancreatic tissue to take care of the digestion of the individual. In a case of mine which was ill for a long time, and finally died, an autopsy was made. After the sloughing of several large pieces of pancreatic tissue, nearly a normal amount of pancreas appeared to be left behind. Of course it is possible that part of what we considered pancreatic tissue was really the peripancreatic fat. Localized abscesses or necroses of the pancreas naturally give better results under drainage than general hemorrhagic pancreatitis.

THE INFLUENCE OF EXHAUSTION UPON PUERPERAL MORBIDITY. BASED UPON A STUDY OF 5,000 PUERPERIA.

BY JOHN T. WILLIAMS, M.D.

(From the Clinic of the Boston Lying-in Hospital.)

THE use of the hospital records for this investigation was opened to me by the courtesy of Dr. Charles M. Green, visiting physician, to whom I desire to express my deep obligation. My interest in this subject was aroused by Dr. Franklin S. Newell's paper, published in conjunction with those of other members of the staff, in reporting and analyzing the first one hundred Cæsareans performed at the Lying-In Hospital.[1] Dr. Newell found that when Cæsarean section was performed after labor had been going on for some hours, complications during the convalescence were more frequent than when the operation was performed before the onset of labor; and that when the Cæsarean was done late in labor, the morbidity was extremely high.

This raised the question of whether similar results should be expected after prolonged labors, terminating either spontaneously or artificially in delivery through the vagina; and, with the hope of answering this, I have undertaken to analyze the records of 5,000 cases delivered in the house clinic of the Boston Lying-In Hospital. In order to exclude factors other than exhaustion so far as possible, cases of eclampsia, placenta previa, detachment of normally situated placenta and patients delivered by Cæsarean section have been excluded, as have also miscarriages, premature labors and patients entering with or developing acute infectious diseases where infection took place previous to labor. With these exceptions, the cases were consecutive in number, confinement number 10,759 being selected at random as a starting point, the final case being number 16,223.

The test of morbidity which I adopted is that in most general use [2] of a temperature over 100.4° F. at any time during the puerperium. Only elevations of temperature during the first ten days have been considered. There are obviously two ways in which exhaustion may influence puerperal morbidity: First, in itself resulting in elevation of temperature and other disturbances; and, second, in lowering the patient's resistance to pathological processes.

THE PHENOMENA OF EXHAUSTION.

Textbook descriptions of the behavior of the temperature after delivery are rather meagre. Williams [3] says: "Not infrequently the temperature may become slightly elevated towards the end or just after the completion of a difficult labor. Under such circumstances it rarely goes above 100.4° F. (38° C.), usually falls to normal within twelve hours and does not rise again. A higher temperature during labor in all probability indicates infection of the liquor amnii." Edgar [4] states that "the temperature is slightly raised by the act of labor. . . . The physiological rise averages about 0.48° F. (0.27° C.). For the first six or seven hours after delivery the temperature continues elevated, and then sinks slowly, so that considerably before the expiration of the first twenty-four hours it has returned to the antepartum point. The temperature curve . . . varies slightly with the period of the day at which delivery occurs."

The journals appear to be lacking in literature dealing directly with this subject. Ryder,[5] writing on "Temperatures Occurring During the Puerperium," describes a reactionary temperature which develops immediately after labor, reaches 101 to 103 and drops quickly to normal. As a result of the careful study of 5,000 puerperia, I am prepared to substantiate in the main the correctness of these statements, but with certain reservations and explanations which a more detailed analysis has made possible.

After 5,000 labors I found an elevation of temperature to 100° F., or higher, at some time during the first twelve hours in 1,025. It was present immediately after delivery in 395 cases, of which, in 335, it fell during the first twelve hours; in 45 rose still higher and in 15 remained the same.

[5] Surg., Gynec. and Obstet., 1907, iv, 48.

(Only bi-daily temperatures were recorded, so that, whether this means that in these latter instances the temperature rose after delivery and was taken by coincidence during the subsequent fall at the same level as at delivery, or whether it actually remained stationary, it is impossible to state. The former would appear more probable.) The temperature rose during the first twelve hours of the puerperium to 100° F. or above in 675 cases,

Charts Illustrating Types of Exhaustion Temperatures.

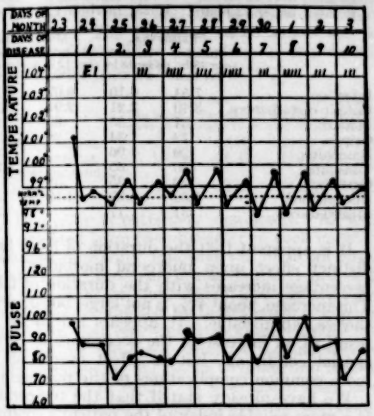

Chart I.

No. 12,940. Primipara. Flat pelvis, twenty-three-hour labor, terminating in spontaneous delivery in the evening. Elevation of temperature immediately after delivery; fall to normal next morning.

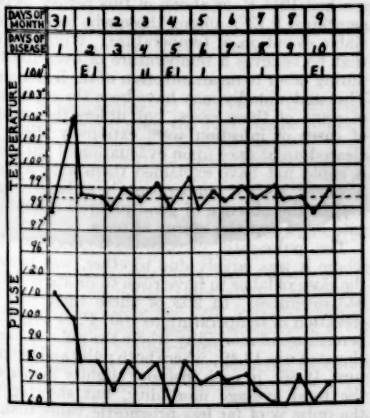

Chart II.

No. 13,936. Primipara. Justo-minor pelvis, twenty-six-hour labor, terminated by high forceps in the morning. Rise of temperature following delivery, reaching climax in the evening; drop to normal the next morning.

and of these only in the 45 already mentioned did the temperature immediately after delivery equal or exceed this mark.

In 23 patients the temperature at delivery reached 101° F. or over, in 20 of these falling during the first twelve hours and in 3 rising still higher. On the other hand, 106 patients experienced a rise of temperature, reaching to 101° F. or higher twelve hours after delivery. Only 26 of these showed a temperature of 100° F. or over immediately after the birth of the child.

It is of interest to inquire into the effect of the time of day at which delivery took place upon the temperature curve, as was referred to by Edgar. Of the 1,025 cases in which the temperature reached 100° F. at some time within the first twelve hours after delivery, 346 were delivered between noon and midnight and 679 during the morning hours. The temperature rose in 81.14% of the latter and fell in 62.46% of the former, showing that the course of temperature is markedly influenced by the diurnal variation. Taking only the instances of a temperature of 101° F. or above, 77.35% of the morning deliveries were followed by a rise and 75% of the evening by a fall. The temperature curve in 1,000 consecutive cases was studied irrespective of height. Morning births numbered 552; afternoon and evening, 458. In 60.86% of the former and 58.45% of the latter the temperature followed the diurnal variation in its curve.

It may, therefore, be said that the temperature during the first twelve hours after delivery is elevated at some time in 20.5%, and that not only in these cases, but in the others, the temperature curve corresponds to the diurnal variation in from 60% to 80%, and is reversed in the remainder. This reversal does not mean a reversal of the bi-daily variation in temperature for the individual, as was shown in practically every case by the subsequent course. Upon what it is dependent this study has thrown no light.

When elevation of temperature occurred, it was not accompanied by any especial or characteristic disturbances. It has most commonly been considered a symptom of exhaustion, although Temesvary [1] has explained it as the result of the increase of blood pressure, following the shutting out of blood from the uterus after expulsion of the child. This temperature is practically always below 100° F. by the end of twenty-four hours. Whatever its cause, the duration of labor does not bear a direct relation to it. Temperatures of over 100° F. occurred in 23.78% of the primiparæ whose labors exceeded eighteen hours in length, and in 25.07% of those in whom the duration of labor fell within normal limits. On the other hand, such temperatures are much more frequent after primiparous labors than multiparous, and are more common in multiparæ who have gone over twelve hours in labor, occurring in 18.6%, as against 14.17% of those in whom labor terminated within its normal duration. In other words, the length of labor is not necessarily an index of its severity, but the occurrence of eleva-

[1] Quoted by Edgar: *Loc. cit.*

tion of temperature does take place in direct ratio to the severity of the labor, being most frequent in primiparous, next most frequent in prolonged multiparous, and relatively infrequent in short multiparous labors. That there should be any such differences were the temperature due solely to circulatory changes seems illogical; therefore it would seem more probable that this phenomenon is to be explained by exhaustion or some other metabolic disturbance directly dependent upon the severity of the labor.

The behavior of the pulse-rate is, on the whole, a less reliable index of the amount of exhaustion than the temperature, since there are so many factors which affect it — pain, excitement, hemorrhage, ether, etc. The pulse-rate was studied in 1,000 consecutive cases. It fell during the first twelve hours in 64.4%, rose in 19.8% and was found at the same level in 15.8%; 66.15% of the instances of rise in pulse-rate accompanied rises in temperature.

THE SECONDARY EFFECTS OF EXHAUSTION.

It is, of course, difficult in analyzing a large series of cases where individual factors of diverse and multiple character must come into play to lay down inflexible standards of judgment for each separate case. On the other hand, the consideration of certain general aspects of this subject must be of the greatest value. We cannot perhaps determine the exact amount of exhaustion in each single case, but we have three very good general indices of it in the duration and character of the labor, the temperature and the pulse-rate after delivery. For the sake of clearness I have considered each of these separately.

The normal duration of primiparous labor is usually stated to be eighteen hours, and of multiparous, twelve, and I have adopted these limits as the dividing line between normal and prolonged labors. Accepting the standard previously laid down, I found the total morbidity, exclusive of temperatures resulting from mastitis, in the entire 5,000 cases to be 11.06%; in 2,687 primiparæ, 12.23%; and in the 2,313 multiparæ, 9.55%. The reasons for excluding mastitis were, first, that exhaustion could hardly be expected to influence inflammation of the breasts; and, second, that the actual result of the investigation showed that it did not.

	Per Cent.
Total morbidity from mastitis,	2.16
Morbidity in primiparæ with labor of over 18 hours duration,	2.48
Morbidity in primiparæ with labor of under 18 hours duration,	2.85
Morbidity in multiparæ with labor of over 12 hours duration,	1.51
Morbidity in multiparæ with labor of under 12 hours duration,	1.51

The greater frequence of mastitis in primiparæ is not due to the greater severity of labor, but rather to the fact that the breasts are being distended and the ducts dilated for the first time, and the nipples never having been hardened by previous nursing are more likely to become cracked.

To show first the relation of the duration of labor to morbidity during the puerperium, I have prepared the following tables, one showing the total morbidity, the other an analysis of the separate conditions:

PRIMIPARÆ.

			Per Cent.
In labor over 18 hours,	968;	morbidity,	14.46
In labor under 18 hours,	1,719;	morbidity,	11.11

MULTIPARÆ.

In labor over 12 hours,	790;	morbidity,	12.02
In labor under 12 hours,	1,523;	morbidity,	8.33

	PRIMIPARÆ.		MULTIPARÆ.	
	In labor over 18 hr. Per Cent.	In labor under 18 hr. Per Cent.	In labor over 12 hr. Per Cent.	In labor under 12 hr. Per Cent.
Infection,	7.54	6.10	6.07	3.74
Enteric disturbances,	3.40	2.21	2.91	2.36
Mental,	.51	.35	.63	.45
Grippe,	.72	.34	.38	.32
Bronchitis,	.20	.06	....	.32
Tonsillitis,	.20	.35	....	.19
Cystitis,	.20	.35	.38	....
Unexplained,	1.32	1.37	1.59	.78
Miscellaneous,	.31	.17	....	.13

It is apparent that the duration of labor has a distinct effect upon puerperal morbidity. The percentage increases with the duration of labor. This increase, about 4%, is not large, but is, nevertheless, appreciable. It appears not to be the result of an increase in the occurrence of certain special conditions, but to affect evenly all the more common complications of the puerperium.

We have already stated that the temperature is a more reliable index of the patient's condition than the duration of labor. The percentage of morbidity among patients having a temperature of 100° F. or over during the first twelve hours after labor was 19.53%; and of those in whom it reached 101° F. or above in this period, 38.09%; as against 9.13% among those who had no appreciable elevation of temperature. Williams [7] says that he believes a temperature of over 100.4° F. during labor to mean infection of the liquor amnii. This undoubtedly may have been the explanation of some of these cases, but unless the majority of cases of infection were extremely slight and cleared up at once upon evacuation of the uterus, it could not have explained them all. At least, however, such a temperature is a danger signal, and in the absence of good progress should indicate emptying the uterus at once.

The pulse-rate, exclusive of operative cases, where it was largely due to ether, was found at the close of labor to have risen to or above 100° in 943 instances. In 202 of these there was also elevation of temperature to 100° F. or over. The percentage of morbidity where the pulse alone was elevated was 13.49; where both pulse and temperature, 13.86; in each instance slightly higher than the total average morbidity, but showing that the pulse is of far less prognostic value than the temperature.

One more point has seemed worthy of investigation, namely, the relative results of early and

[7] *Loc. cit.*

late interference as regards the smoothness of convalescence. I have classified as high operations all interference at or above the brim, no matter what the presentation or method of delivery. I have also classified manual extraction of the placenta as a high operation, for this should be rightly considered a major obstetric operation. Following the custom at the Lying-In Hospital, which does not recognize the term "intermediate forceps," all cases of interference after the presenting part had passed through the brim have been termed low operations. These were chiefly forceps. The high operations altogether numbered 268; the low, 524; and the spontaneous deliveries, 4,208. The following table shows the percentage of morbidity according to the duration of labor and the method of delivery.

	Primiparæ.		Multiparæ.	
	In labor over 18 hr.	In labor under 18 hr.	In labor over 12 hr.	In labor under 12hr.
High operations,	27.63	25.88	24.59	20.63
Low operations,	16.94	11.47	11.76	5.55
Spontaneous deliveries,	20.88	12.80	14.22	9.41

This table is extremely significant. As would be expected from the character of such cases, the greatest morbidity followed the high operations. Here again, however, it was in direct proportion to the length of time which had elapsed before labor was terminated by interference. This does not mean that one should recklessly interfere too early before the birth canal has had an opportunity to soften up, the cervix to dilate and the child child's head to mold. It does mean that in delayed labors one should operate for the sake of the mother as early as is consistent with the safety of the child. Still more significant is the relative morbidity of spontaneous delivery and low forceps. The consistently and decisively better results of shortening labor by the use of forceps when the head is low are certainly striking. They are undoubtedly due to the lessening of exhaustion from pain and muscular effort.

CONCLUSIONS.

1. A temperature of 100° F. or above occurs at some time during the first twelve hours after delivery in about 20.5% of all cases.

2. The temperature curve during this period in the majority of cases corresponds with the diurnal variation.

3. This elevation of temperature does not necessarily correspond to the duration of labor, but probably does to its severity.

4. The pulse-rate is a less reliable index of exhaustion than the temperature. It most commonly falls during the first twelve hours, a rise in the majority of cases accompanying a corresponding rise of temperature.

5. Puerperal morbidity, with the exception of mastitis, increases in direct proportion to the duration of labor.

6. This increase affects equally all the more common complications of the puerperium.

7. Cases in which there is an elevation of temperature during the first twelve hours after delivery are followed by a higher morbidity than those in which there is not; and when this temperature reaches to 101 or over, the subsequent morbidity is 38.09%.

8. An elevation of pulse at the end of labor is of comparatively slight prognostic importance from this standpoint, but is followed by a slightly increased morbidity.

9. The morbidity is greatest after the high operations, but here, as is also true of the low operations and spontaneous delivery, the morbidity increases in direct proportion to the duration of labor.

10. The morbidity after low forceps is less than after spontaneous delivery, presumably because labor is shortened and exhaustion lessened.

11. From every standpoint from which it has been considered, it is evident that exhaustion during labor has a distinct influence toward increasing puerperal morbidity.

THE VALUE OF TUBERCULIN IN TUBERCULOSIS OF THE URINARY TRACT.*

BY HUGH CABOT, M.D., BOSTON.

The use of tuberculin as a curative agent has been on trial for many years, but its use in lesions of the genito-urinary tract is comparatively recent. This is certainly true of its successful use, and is probably due to the fact that our knowledge of these lesions has increased rapidly of late years and we have, therefore, been able to use tuberculin with better understanding and in more appropriate cases. In general, its use is not to be advised, and little benefit can be expected in the presence of massive tubercular lesions, from which constant reinfection can occur. More recent knowledge has enabled these lesions to be dealt with surgically, leaving only a modicum of the disease in which milder measures may be effective. In our experience the brilliancy of the results has been inversely proportionate to the severity of the disease, and tuberculin has been chiefly valuable in stamping out the secondary processes in the bladder and ureter.

The cases in which we have used it may be divided roughly into two classes:

(1) Those in which the disease has been apparently completely removed, as in unilateral kidney infections without bladder involvement. In these cases its use has resulted in permanent and prompt wound healing, in contrast to cases in which a sinus follows operation, leading either to the stump of the ureter or to the pedicle. While cases of this type usually recover under ordinary methods, it has seemed that tuberculin saves much time and anxiety to the patient.

(2) Those cases in which though the principal focus of the disease has been removed, a certain amount still remains. As types may be taken, the unilateral kidney lesions with bladder involvement and unilateral lesions of the epididymis and vas, with involvement of the prostate. It is this class of cases to which I particularly wish to call

* Read before the New England Urological Society, March 8, 1910.

your attention, as their after-treatment by other methods has, with us at least, been unsatisfactory and we have regarded tuberculin as a distinct addition to our methods of treatment.

In treating cases of the first class we have for the past year been giving tuberculin after the method advised by Trudeau to all cases of nephrectomy or epididymo-vasectomy for tuberculosis, beginning immediately after operation. This has resulted in perfect wound healing and a noticeable absence of troublesome sinuses, which we have so often seen in the past.

TECHNIC.

This is essentially that advised by Trudeau and that which has been used here in the tuberculosis classes at the Massachusetts General Hospital by Dr. John B. Hawes, to whom we are indebted for advice. The preparation used is a bouillon filtrate kindly furnished by Dr. Trudeau. Injections are begun with minimal doses, generally about .005 mgm., a dose so small as not to produce a reaction in these cases. The dose is fairly rapidly increased until 0.1 mgm. is given, the interval between injections at first being three or four days, later about a week. The injections are continued and the dose increased until the patient receives 10 mgm., always provided no reaction occurs. This point is ordinarily reached in about three months, when in cases of the first class the injections are discontinued and the patient discharged. In cases of the second class, the injections are generally continued at a maximum dose until the patient is free from symptoms, or six months have elapsed. Then we have generally discontinued the injections in order to get the benefit of intermittent rather than continuous treatment. In some of the cases with larger doses, reactions both local and general have occurred, but these seem to have done no harm, and in some instances have been followed by distinct benefit.

At present our cases are too few to warrant detailed conclusions, but in all there has been some relief of the symptoms, and in many the relief has been very marked.

The following are histories of three cases of somewhat different types, but all belonging to the second class:

Mrs. E. A. E., thirty-five. In 1905 began to have painful and frequent micturition. In August was laid up in a hospital in Montreal on account of her bladder. In October, 1906, came under the care of Dr. F. S. Watson, who found a suppurating left kidney. Her condition was so poor as to permit only a nephrotomy which showed the process to be tubercular. During the next year she improved considerably and in October, 1907, cystoscopy showed ulceration about the left ureter, and catheterization of the right ureter showed a normal kidney on that side. In November, 1907, the remains of the left kidney were removed by Dr. Watson. During the subsequent two years the patient's general condition improved, but the bladder remained very irritable in spite of various forms of local treatment. In May, 1909, at the request of Dr. Watson, she was started on tuberculin. The symptoms showed prompt improvement to an amount which had been unattainable by other methods. The tuberculin has been continued somewhat intermitttently to the present time. She is now fairly comfortable except that the bladder capacity is still small. Though far from well, she is much improved.

Miss B. E. P., twenty-two. Seen Dec. 1, 1908. Patient of Dr. M. H. Richardson. About five years ago began to have frequency of micturition. This has slowly increased until during the last six months it has become intolerable. Cystoscopy shows bladder contracted to 3½ oz. Left ureteral orifice dilated, but kidney doing good work. Right kidney practically doing no work. Dec. 10: The right kidney was removed and found entirely destroyed. The left kidney was explored and appeared substantially normal, though considerably enlarged, and with a much dilated ureter, the cause of which I am unable to explain. Patient improved markedly after operation, but considerable bladder irritability remained. In October, 1909, she was started on tuberculin. The pain and frequency promptly disappeared, the bladder capacity increased from 7 to 14 oz. and the urine improved very much. Tuberculin was continued until January, 1910; since that time she has remained in a comfortable condition and there seems to be no indication for treatment.

Mr. A. H. Y., forty-two. In January, 1908, began to have frequency of urination without obvious cause. In June, 1908, left epididymis became swollen and tender. He was more or less confined to the house for the next three months. Bladder irritability very variable. First seen April, 1909, on account of persistently cloudy urine. The left epididymis was enlarged, hard and nodular. The vas was thickened as far as the external ring. Prostate not apparently abnormal, though probably involved. The left epididymis and vas as far as the brim of the pelvis were removed. Tuberculin was begun in the latter part of May, 1909. The wounds healed promptly and have given no further trouble. The urine promptly cleared up, the frequency of urination practically became normal, though he has continued to have recurrent attacks of frequency, with a little pus in the urine. He is still under observation and on treatment with tuberculin. His general condition is excellent. There has been no further involvement of the prostate or the other epididymis, but there is still evidently some disease in the prostate, as from time to time he has frequent urination.

BACTERIAL VACCINES IN PYOGENIC INFECTIONS OF THE URINARY TRACT.*

BY H. P. HASTWELL, M.D.

THE report which I have the pleasure to present to-night is based on the results obtained in the use of bacterial vaccines in twenty-five cases of infections of the urinary tract treated at the Massachusetts General Hospital. As the colon bacillus has been the micro-organism present in almost all of them, I shall speak only of the vaccines of this bacillus, although the few cases where other pyogenic bacteria have been found, for the most part streptococci and staphylococci, have shown the same outcome under treatment with their autogenous vaccines, and the observations in regard to colon vaccines may, therefore, be applied to those of other pyogens as well. The presence of tubercle bacilli has been excluded in all by the injection of sediment into guinea-pigs.

In those cases of colon infection which com-

* Read by invitation before New England Urological Society, March 8, 1910.

monly occur in females, more especially in young girls, where the anatomical lesion seems to be a pyelitis or a pyonephritis, the treatment with vaccines in our hands has been completely unavailing. In their chronicity these cases may be compared to typhoid carriers, for in some the infection has been followed for several years. At irregular intervals they suffered acute attacks of lumbar pain, with chills, fever and frequently bladder irritation. When these acute symptoms subsided, they would be subjectively well, passing cloudy urine with pus and colon bacilli. X-ray for stone was always negative, and the cystoscope showed mild cystitis which was most marked about the ureter of the affected side. Bacterial vaccines had no effect in preventing acute exacerbations nor in lessening the amount of pus or bacilluria. Treatment was continued in all for six months, and in some for a year, with every variation in dosage and in the spacing of inoculations that seemed worthy of trial. In order to make more clear the obstinacy and the fruitless results of treatment in these cases of bacilluria, I should like to cite briefly the following history:

A Jewess, twenty-one years old, was admitted to the wards June 2, 1908. She had been married two weeks before, and a few days after had painful and frequent micturition with burning. These symptoms soon subsided, and a week later she had severe pain along the right costal margin and in the right loin. There were chills with fever and a high pulse, tenderness and rigidity in the right upper quadrant, and tenderness at the right costo-vertebral angle. Urine cloudy, albumen slightest possible trace, sediment, many pus cells, few red and squamous cells, no casts. Culture, profuse growth colon bacilli. At operation the right kidney was exposed, the surface found studded with small abscesses, and the capsule was split. Culture from surface of kidney showed colon bacilli. July 13 she was seen in the Out-Patient Department complaining of pain in the right side, with frequency and painful micturition. The right kidney was enlarged and tender. Several x-ray plates were negative. Cystoscopic examination by Dr. Lincoln Davis showed normal bladder with normal ureters. Indigo-carmine test slightly delayed action in discharge of pigment from right ureter. A few cubic centimeters of urine collected from each kidney by ureteral catheter showed colon bacilli in both. Treatment with an autogenous vaccine was begun and was continued till the middle of May, 1909, without any improvement in the symptoms nor in the condition of the urine. While under vaccine treatment she had several attacks of severe pain in the right side, with chills and fever, which forced her to bed. In November, 1908, an abortion was done when she was two months pregnant, as it was thought that it was not safe to let her go to full term. In December, 1909, she had a normal labor at the Boston Lying-In Hospital, and during the puerperium an attack of pain in the right side with rise in temperature lasting twenty-four hours. When last seen, on Jan. 3 of this year, her symptoms were unrelieved. The urine showed 1-10% of albumen, with pus and many small round cells single and in clumps, numerous hyaline and granular casts. Culture profuse growth colon bacilli.

In the acute and the subacute infections of the kidney pelvis, bacterial vaccines seem to offer promising results, but we venture this statement with reserve, as our cases have been too few to make any definite assertion. As an example, I would like to give the following history:

A woman thirty-five years, admitted to the wards April 6, 1908, giving a history of severe bladder pain with hematuria coming on suddenly ten days before. A few days later pain was felt in the right kidney region and soon after in the left. Temperature, 103.6; pulse, 90. Examination showed rigidity in both upper quadrants and tenderness in the flanks over both kidneys. Cystoscopic examination by Dr. Davis showed bladder reddened and injected, with ulcerations. Pus from left ureter. Indigo-carmine test showed delayed action on both sides, especially on left. Urine, acid, 1012; albumen slight trace, sediment, pus, squamous and round cells, no casts. Culture, profuse growth B. coli. She was treated in bed with bladder irrigations and given urotropin. The temperature fell to normal. April 13, vaccines were started. April 19, an improvement in her general condition was noted. Her pain was much less and there was less sediment in the urine. May 14, she was discharged to the Out-Patient, where vaccine treatment was continued. Culture of urine showed a slight growth of B. coli. June 3, complained of slight pain in left kidney region, but examination showed no tenderness nor rigidity. Cystoscopic examination: Bladder normal, slight edema about ureteral orifices, which are otherwise normal and functionate normally. Urine clear, culture showed no growth. We were unable to trace this patient after her discharge, so we cannot state the permanency of the result.

One case in this series had an irritable bladder from an infected ureter stump left after nephrectomy for chronic pyelitis. Treatment with bladder irrigations and urotropin was without influence on his condition, but he has shown marked and continued improvement with vaccines.

In all cases of nephrotomy with drainage of large pus sacs, vaccines produced no impression on the local suppuration and had no influence in diminishing the septic absorption.

The milder cases of bladder infections have responded well to treatment with bacterial vaccine. Some who had first received urinary antiseptics and irrigation were afterwards given vaccine treatment alone, and their improvement seemed more striking and rapid with vaccines. After the first few inoculations, the irritation, frequency and pain were lessened and diminished steadily as treatment progressed. The condition of the urine showed a corresponding but slower improvement. The bacilluria, as in the kidney infections, was very obstinate. In a few of the bladder cases, a bacteria-free urine was obtained after a prolonged treatment, but usually this was accomplished only in conjunction with a urinary antiseptic. In all of them where the urine was examined four to six months after they had been discharged bacteria-free, a slight bacilluria was again found, although they were symptomatically well.

In the severe case of cystitis, where there were marked changes in the bladder wall and mucosa, vaccines did not appear to have any effect.

From an experience with this small number of cases of urinary infections, I should say that vaccines were indicated in acute pyelitis which

does not respond well to ordinary measures. They will probably furnish us a means of attacking post-operative foci, such as an infected ureter stump, which are difficult otherwise to clear up. In cystitis, in a limited number of cases, they offer a less troublesome, possibly a more rapid, therapy than that by irrigations and urinary antiseptics.

Clinical Department.

PERSISTENT VOMITING OF PREGNANCY.

BY F. W. JOHNSON, M.D.,

Gynecologist-in-Chief, Carney Hospital.

DECEMBER, 1907, Mrs. A. H. entered the Carney Hospital two months pregnant. She had been vomiting pretty constantly for the three weeks previous to entering. At the time of entrance there was constant nausea, with inability to keep anything in the stomach. There was an appetite. The bowels were constipated. Water and all nourishment was stopped by the mouth. Every two hours a minim of iodine and creosote in ten minims of water were dropped on the tongue. In two days vomiting had ceased entirely and nourishment was begun by the mouth. There was no more vomiting and she went without further trouble to full term.

April, 1910, she again entered the hospital three months pregnant. For ten days there had been constant nausea and inability to retain anything in the stomach. Water and all nourishment was stopped by the mouth. Oxalate of cerium was tried with no good result; then 5 gr. of Burrough's Welcome & Co.'s thyroid extract was tried by the mouth every eight hours with little improvement. The extract seemed to cause nausea. Five gr. of the extract were then given subcutaneously every eight hours with immediate relief.

Medical Progress.

REPORT ON PROGRESS IN OTOLOGY.*

BY HARRIS PEYTON MOSHER, M.D., BOSTON.

(Continued from No. 11, p. 440.)

INTRACRANIAL COMPLICATIONS OF OTITIS MEDIA.

THE symptoms and treatment of brain abscess are given. In serous meningitis, which McKernon[6] says is not an infrequent complication of extensive mastoid or sinus disease, lumbar puncture is given as an important aid in both diagnosis and treatment. In purulent leptomeningitis, early operation and drainage are the most hopeful measures. Cushing's suggestion of the use of urotropin to render sterile the micro-organisms is emphasized.

CEREBRAL ABSCESS.

Taylor[7] discusses cerebral and cerebellar abscesses and particularly makes the point that, in these days of diagnostic lumbar puncture, great caution must be displayed in using it, in the presence of cerebral or cerebellar abscess, lest the altered conditions of tension lead to rupture of the abscess into the membranes.

OTITIC BRAIN ABSCESS.

Sachs and Berg[8] discuss in this article the difficulties of brain abscess with special reference to drainage. Localization is most common in the temporosphenoidal lobes or in the cerebellum. If in the former, there will be, in addition to general symptoms, headache, somnolence, nausea and vomiting and slight optic neuritis, some hemiparesis and impairment of speeech perception. Sensory aphasia is a common accompaniment of otitic brain abscess in the temporosphenoidal lobes. Right temporosphenoidal abscess is sometimes associated with dysarthria, not with sensory aphasia. Abscess in the cerebellum, in addition to general abscess symptoms, may show cerebellar ataxia, diminution or increase of deep reflexes, abducens paresis, acoustic nerve symptoms and possibly cerebellar seizures. The motor area is rarely the seat of otitic brain abscess, wherefore the author's second case reported in this article is important because it proves that an undoubted otitic abscess may involve the motor area. The three main considerations from a surgical standpoint are: (1) A wide exposure of the area of the brain in which the abscess is supposed to lie. This is best done by raising an osteoplastic flap. (2) A most important consideration is the protection of the meninges against infection by the purulent contents of the abscess cavity. If this lies near to the cortex of the brain, or on it, it is more than likley that the meninges will be protected from infection by a barrier of natural adhesions that have formed before the operation is done. These are the most favorable cases for surgical interference. (3) Proper drainage of the abscess cavity. Here we must remember that there are two entirely different kinds of abscess cavities in the brain — one with soft walls that readily collapse when the contained pus is evacuated, and the other with rigid walls that show no tendency to fall together and that must be obliterated by the slow process of granulation. In the former, all that is required is the establishment of drainage by a thin slip of rubber tissue at the most dependent point of the cavity. In the latter, the drainage must be by a tube of some kind, whether rubber, decalcified bone or other material, according to the choice of the operator. This tube must be inserted at the lowest point of the abscess cavity, otherwise there is bound to be retention of pus.

CEREBRAL SURGERY.[9]

The special points of technic on which he lays stress are, first, the anesthesia, with the complete shutting off of the anesthetist from the operative field, which he accomplishes by means of an arrangement of the operative sheets that completely cuts off the anesthetist. He secures

* In compiling this Report on Progress in Otology for the last year the reviewer has made extended use of the *Index Medicus;* of nose, throat and ear literature compiled and published by the editor of the *Laryngoscope* in the issue of March, 1910. The reviewer wishes to thank Dr. Goldstein for his admirable and most useful publication.

[6] J. F. McKernon: Jour. Am. Med. Asso., Jan. 9, 1909.

[7] W. Taylor: Med. Press and Circ., Jan. 20, 1909.

[8] B. Sachs and A. A. Berg: Med. Rec., Jan. 23, 1909.

[9] H. Cushing: Jour. Am. Med. Asso., Jan. 16, 1909.

free respiration in the prone position by a special form of outrigger to the operative table. The continuous auscultation by the anesthetist of the cardiac and respiratory action is also provided for by a phonendoscope attached to the patient's chest by adhesive strips and connected with the anesthetist's ear by a device like the head gear of a telephone operator. This he considers especially important. The next thing mentioned is the subtemporal decompression trepanation as an early measure in case of possible brain tumor that cannot be exactly localized. This is performed in a safe area and is often of itself sufficient to relieve symptoms. If localizing signs appear later, the removal operation can be performed. While in tumors above the cerebellum lumbar drainage is invaluable, Cushing calls particular attention to the dangers of lumbar puncture in cases of subtentorial tumors, from forcing down the brain substance into the spinal canal. The possibility of an unsuspected cerebellar growth, he thinks, should always be kept in mind, and the puncture not made unless the dura is exposed and ready for immediate opening in case medullary symptoms supervene. This leads him to speak of the value of a bilateral opening with wide exposure in other cases of growths difficult of access, which is also useful in preventing compression or mutilation of cerebral tissue in operation. In the older high operations for removal of Gasserian ganglion, there was also much of compression and contusion of the temporal lobe, although no tumor was already compressing the brain, and Cushing gives special cautions for this procedure. He is able to report seventy-four operations with only two deaths, and he prefers the simple evulsion from the pons of the sensory root alone, leaving the ganglion in its bed with a half-inch gap between its hinder border and the original pontine attachment, a gap he thinks not likely to be bridged, even admitting the possibility of a central regeneration.

CRANIAL TECHNIC.

Dr. Hartley[10] enumerates the following as the prime requisites for avoiding the dangers of shock and sepsis in operations on the brain: (1) Instruments which will open the skull quickly over any desired area and to any extent. These are the motor, saw and guard, osteotome, drill, fraise and measure. (2) A method of cranio-cerebral topography permitting an accurate exposure of the desired area. Chipault's is the best method, as it is adapted to the skull of all ages, races or individual peculiarities. (3) Osteoplastic flaps cut so that they will expose the desired area in the easiest manner. (4) The replacing of the bone flap in every possible case, or covering the defect with an accurately fitting foreign material (celluloid or aluminum). He prefers autoplasty when possible. (5) The most perfect hemostasis in the preliminary as well as in the final steps of the operation. The operation he divides into two steps, the first concerned only with the skull, the final with the dura and brain. All drugs should be given up several days before operating, and a record of pulse-rate and blood pressure should be taken twenty-four hours before operation. The patient's head is raised on the table between 15 and 30°, which Hartley has found sufficient to stop venous bleeding and lower arterial pressure. He has not been able to compare the effects of Crile's rubber suit and carotid compression or of Dawbarn's sequestration-anemia with this, but if they will improve the arterial pressure better than elevation and with no greater danger of inducing sudden syncope, he willl certainly use them. During the operation he would have the blood pressure recorded by the anesthetist by a sphygmomanometer on the arm, as a sudden fall will warn the operator of any impending sudden collapse and will probably enable us to avoid the 25% of sudden deaths following prolonged operation. The details of the operation are given and the necessity of careful hemostasis during the second stage emphasized, as well as the importance of avoiding infection of the lateral ventricles. Possible later complications are: (1) Shock, in prolonged operations with hemorrhage or after large tumors have been removed and the cerebral statics disturbed by the space left. In such case the acute cerebral edema of Von Bergmann occurs. To avoid this Hartley tampons and gives counter pressure through the flap. (2) Hyperpyrexia: This occurs after both severe and moderate handling of the brain, especially if the ventricles have been opened, and is due to toxicity of the neoplasm secretion, infection, or irritation of thermic centers in the bulb. (3) Encephalomeningitis may be due to injury or to infection from the patient's blood or without. It usually appears during the first month after operation, coming on slowly, with localized convulsions, contractures, paralysis, somnolence, mental torpor or delirium. (4) Hernia may be present at the time of operation as a tumor of the base or as a voluminous tumor of the centrum ovale, or at a later period in the form of encephalitis.

[10] F. Hartley: Jour. Am. Med. Asso., Jan. 9, 1909.

THE PHYSIOLOGY AND PSYCHOLOGY OF HEARING, WITH SPECIAL REFERENCE TO DEVELOPMENT OF SPEECH.[11]

How are sound waves transmitted from the labyrinthine fluid to the auditory nerve, and what particular changes take place in them during this transmission? Helmholtz was the first to offer any definite solution to these problems, and for many years his resonance or piano-string theory was accepted as being the most satisfactory. At first he thought that the rods of Corti respond to different notes, as do the strings of a piano, but when it was shown that some animals have no rods, he transferred this function to the fibers of the basilar membrane. It was supposed that this membrane, because of its position and peculiar

[11] G. Hudson-Makuen: Laryngoscope, vol. xx, no. 6, p. 612, June, 910.

structure, served the purpose of receiving the sound waves, selecting them according to their adaptation to its transverse fibers, which increase in length from the base of the cochlea to its apex; that the high tones were perceived by the shorter fibers at the base and the lower ones by the correspondingly longer ones towards the apex, and that the responsive vibrations were taken up by the hair cells resting upon the membrane, where they were changed into impulses suitable for conduction by the auditory nerve to the hearing center of the brain.

This was an ingenious theory, but it has not stood the test of time, for neither in its structure nor in its size has the basilar membrane been found to meet the requirements which Helmholtz imposed upon it. The transverse fibers are not sufficiently numerous to produce the range of pitch that the human ear is capable of perceiving, and their disposition in relation to the longitudinal fibers and various blood vessels makes it physically impossible for them to vibrate after the manner of piano strings. Moreover, it has been found that the membrane does not extend to the lowermost part of the cochlea and that the hair cells in this region do not come in contact with it, and, therefore, cannot transmit its vibrations to the neuro-epithelial cells, where they are supposed to be transformed into nerve impulses.

This latter objection to the piano-string theory seems also to be opposed to the so-called telephone theory, which regards the basilar membrane as a kind of second drum membrane between which and the tectorial membrane the so-called "pressure patterns" are made which impart their vibratory motions to the hair cells. This theory supposes that the analysis of tone or the perception of pitch takes place in the cerebral cortex, while the piano-string theory locates this function in the cochlea.

In addition to the anatomical objections to the two basilar membrane theories which have mentioned, there seems to be good phylogenetic, ontogenetic and histological reasons for the entire abandonment of this membrane as a conspicuous factor in the transmission and perception of tone and for the substitution of the tectorial membrane in its stead. On account of the extreme delicacy of the tectorial membrane, however, the difficulties of demonstrating absolutely the exact manner in which it performs this function are almost insurmountable, and we can only say that it appears in all respects to be better adapted to the functions which have been described.

AURAL COMPLICATIONS IN THE EXANTHEMATA.

The author [12] concludes his paper as follows: In scarlet fever, children are quite liable to middle-ear inflammation which may or may not involve the mastoid cells. Adults are much less so, and rarely have mastoiditis. In measles, both adults and children are very susceptible to middle-ear involvements, and adults are especially in danger of mastoiditis. In cases where a tremendous aural discharge is present for more than two or three weeks, the mastoid operation should be seriously considered as a means of providing drainage, since it is more efficient than a small pin-hole perforation in the delicate membrana tympani. Occasionally a case will arise in which the diagnosis may be difficult. If after carefully ruling out every other possible cause by exclusion, the mastoid remains in doubt, and the symptoms of the patient are at all serious, it is better to operate. The danger is greater from waiting. If after the acute symptoms of scarlet fever and measles have subsided, pus in the middle ear is kept active by profuse nasal or nasopharyngeal discharges, the physician should examine the patient for adenoids. If these growths are present, they should be removed. This procedure in the course of diphtheria, however, is questionable.

STUDY OF THE EUSTACHIAN TUBE IN ITS RELATION TO THE RADICAL MASTOID OPERATION.

Oppenheimer [13] states that, in order to remove all sources of infection in the radical mastoid operation, the tympanic end of the Eustachian tube should be made surgically clean by causing its obliteration. This may be done at the time of the operation or during the after-treatment. When curetting the tube during the operation, small oval or round curettes should be used, so that they can pass into the mouth of the tube. As far as possible all diseased bone and diseased mucous membrane should be removed. Great care, however, should be exercised in doing this in the region of the carotid canal as dehiscences may be present and the artery injured seriously. If skin grafting be employed at the radical operation, the epidermis should be forced well into the tube so that the parts of the tube which have been deprived of their mucous membrane by the curetting will be thoroughly covered.

PURULENT DISEASES OF THE EUSTACHIAN TUBE.

The author [14] concludes as follows: Those cases of middle-ear suppuration in which the perforation is situated in the anterior inferior part of the drum membrane, and which have been considered to be due to disease situated around the tympanic orifice of the tube, or to nasopharyngeal disease, are in reality due to suppuration of the tube itself and should be called "tuborrhea." This condition is characterized by a wide open tube, due to relaxation. Such cases should be treated by irrigation of the tube through the Eustachian catheter. The relaxed tube is treated by passing a roughened bougie through it and by massaging it. Reinfection is apt to occur, but it responds readily to a repetition of the treatment.

THE ISTHMUS OF THE EUSTACHIAN TUBE. A CONTRIBUTION TO THE PATHOLOGY AND TREATMENT OF MIDDLE EAR DISEASES.

Yankauer,[15] in an exhaustive article on the isthmus of the Eustachian tube, makes the follow-

[13] S. Oppenheimer: Med. Rec., Dec. 25, 1909.
[14] E. Urbantschitsch: Monatsschr. für Ohrenh., vol. xliii, heft. 7, 1909.
[15] Sidney Yankauer, M.D., New York: Laryngoscope, July, 1910, pp. 675–718.

ing points: The pharyngeal portion of the Eustachian tube is homologous with the nasopharynx and must be considered a part of it. The tympanic portion of the tube is homologous with the tympanic cavity, and it should be regarded as a part of it. The portion of the Eustachian tube previously known as the bony portion could be called appropriately the pretympanum. The most important part of the tube is the isthmus. This may be reached for diagnostic or operative purposes first from the pharyngeal side through the Eustachian catheter and, second, through the external auditory canal through an incision made for this purpose in the anterior inferior part of the drum membrane or through a perforation previously existing as a result of disease.

After making these statements Yankauer describes the method of reaching the Eustachian tube through the catheter and describes and figures his applicators and sounds. By means of an applicator he applies cocaine and adrenalin to the tube and then dilates with bougies if a stricture is present, or, if acute or subacute inflammation of the mucous membrane exists, applies argyrol in solutions as high as 50%. In acute inflammation of the middle ear he has opened up the Eustachian tube in this manner and medicated it and feels that he has aborted a certain number of cases of impending suppuration. Following this procedure he states that there is immediate cessation of the throbbing earache and tinnitus. If the inflammation be of a mild degree, or if the case is seen in its earliest stages, before redness and bulging of the drum membrane are present, the relief obtained will be permanent and the disease will be brought to an immediate and abrupt termination, often by one application. In the terminal stages of acute otitis media, when the discharge has ceased and the perforation has closed, but when deafness, tinnitus and fullness in the ears persist, the use of intratubal applications of argyrol yield prompt and definite results. In subacute inflammation of the middle ear, especially those cases characterized by serous or seromucous fluid in the tympanic cavity, cases which have hitherto been found to be obstinate under the usual methods of treatment, the application of argyrol has been found to be very efficacious. The writer has devised a routine plan of treatment of the isthmus of the tube, which may be summed up as follows: (1) The application of cocaine and adrenalin solution to the region just beyond the isthmus. (2) The passage of the largest possible sound and its retention for five or ten minutes. (3) The application of a 50% solution of argyrol to the region beyond the isthmus. (4) The inflation and deflation of the middle ear.

Feeling that strictures of the Eustachian tube could be dealt with best through the external auditory canal, and arguing from the fact that when the radical mastoid operation fails to cure suppuration the fault usually lies in a failure to close the Eustachian tube, Yankauer proceeded to close the tube at the isthmus in a number of cases of chronic suppurarion of the middle ear. Some of the cases had been advised to have the radical operation performed, but had refused. In these cases there was no operative middle-ear treatment beyond the removal of polyps, so that the procedure of closing off the Eustachian tube at the isthmus could be more easily carried out. Some 21 cases were operated upon, and of these 13 were cured. Of these, 12 were examined a month before the paper was written and were found to have remained well, 2 for three months, 1 for seven months, and the rest for one to two years. In many cases of chronic middle-ear suppuration, therefore, Yankauer believes that the tube is a more important factor in keeping up chronic middle-ear suppuration than necrosis of the ossicles or even disease of the mastoid antrum. His recorded cases certainly seem to bear out his view, and it is to be hoped that his results will be substantiated immediately by other observers.

Yankauer closes the Eustachian tube by working through the external auditory canal. By experimental work upon the cadaver he has devised appropriate instruments for the procedure.

The paper ends with a striking observation. After closure of the Eustachian tube at the isthmus, Yankauer found that existing perforations in the drum not only failed to heal, but actually grew larger. With this observation in mind he operated upon several cases of otosclerosis, hoping that by letting more sound waves in upon the stapes the hearing would improve. This he found to be true. The new point in his cases, however, was the fact that the perforations made in the drum did not close as they invariably did in the older experiments of a similar nature, but they remained open. This is an observation the clinical importance of which is very considerable.

Reports of Societies.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

THIRTY-FOURTH ANNUAL MEETING, HELD AT THE ARLINGTON HOTEL, WASHINGTON, D. C., MAY 3, 4 AND 5, 1910.

FIRST DAY, TUESDAY, MAY 3.

(Concluded from No. 11, p. 444.)

MYCOSIS FUNGOIDES, WITH REPORT OF A CASE.

DR. LUCIUS C. PARDEE and DR. ROBERT F. ZEIT, of Chicago. In summing up the various features presented in this report, the authors said there could scarcely be any doubt that the case was clinically one of mycosis fungoides. All the classical features of this disease, as described by numerous observers, were present. The premycotic or prefungoid stage was marked and extended over a known period of at least two years. The lesions at that time were typical of the well-known erythematous form and were accompanied by the usual intense pruritus. These were followed in the course of time by the formation of fungoid tumor masses on various portions of the body which macroscopically had the aspect ordinarily described as that of small round-

celled sarcomata and which underwent the usual course of development, with occasional retrogressions. The blood findings were those of progressive anemia until toward the end of life, when the characteristics of a lymphatic leukemia were rapidly added and dissolution followed. The autopsy developed the findings of lymphatic leukemia, plus the gross aspect of mycosis fungoides.

DR. JAMES NEVINS HYDE, of Chicago, said the post-mortem findings in the case reported by Drs. Pardee and Zeit were quite unusual and had set a new record in connection with mycosis fungoides.

DR. A. RAVOGLI, of Cincinnati, said it seemed that this disease had different ways of appearing, and also varied in its course. In some instances it was of a sarcomatous nature from the outset, while at other times the eczematous premycotic condition existed for a long period before the appearance of the tumors.

DR. H. W. STELWAGON, of Philadelphia, said these peculiar sarcomatoid cases could be divided into three general groups: First, we had the frank generalized sarcomatosis, under which Kaposi placed all these groups: then we had the cases of leukemia and pseudo-leukemia with cutaneous symptoms, to which the one reported in Dr. Pardee's paper seemed to be closely allied; and, third, we had the cases of granuloma fungoides. The last certainly had seemed distinct from any leukemic process.

DR. WILLIAM A. PUSEY, of Chicago, thought this case apparently belonged to the type that we classified as mycosis fungoides. Furthermore, it showed a definite connection between mycosis fungoides and leukemia.

DR. PARDEE, in closing, said that, as far as the internal findings of mycosis fungoides were concerned, it seemed to him that this phase of the subject had not been thoroughly looked into in many of the cases that were on record; otherwise, perhaps, the association of the skin lesions with changes in the internal organs would have been more frequently found.

FIBROMA MOLLUSCUM, OR UNIVERSAL NEURO-FIBROMATOSIS.

DR. A. RAVOGLI, of Cincinnati, detailed a case of this kind which was reported on account of its relative rarity. The affection seemed to be a congenital one. The mollusca ranged in size from that of a pinhead to a hazel nut and were scattered over the entire body. The lesions showed no relation to the lines of the skin, nor to the underlying nervous ramifications. The tumors had their origin in a deep subcutaneous nodule. After reaching their full development, they underwent degeneration, gradually disappearing and leaving a pigmented spot. It was apparently a disease of the nervous system, involving the terminal filaments of the cutaneous nerves.

DR. WILLIAM S. GOTTHEIL, of New York, said that while neurofibromatosis was a well-sounding name, the question was whether it was appropriate. In the cases that he had seen and examined, in the small tumors they found something which they could not demonstrate as anything but pure fibroma, without any connection with the nerve sheaths. In the larger growths there was myxedematous degeneration. In none of his cases did they find any distinct connection with the sheaths of the nerves, and there were no nerve fibers in the tumors.

DR. LOUIS A. DUHRING, of Philadelphia, said that in this disease, as in mycosis fungoides, we had several varieties and aberrant types. In the so-called Recklinghausen's disease the pigmentation was marked, and it was in this degree of pigmentation that they chiefly differed from the other types so familiar to observers. The majority of these cases might be classed under the head of simple fibroma molluscum, and thus differentiated from neurofibromatosis. In the average case of the former there were no subjective symptoms, and in the course of the disease there might in time be retrogressions or other changes.

DR. RAVOGLI, in closing, said that most of the writers on this subject did not make much distinction between fibroma molluscum and neurofibromatosis. In his own case, the lesions had their origin from a deep, subcutaneous nodule, developing into peculiar growths which were composed of connective tissue fibers, and for that reason he called them fibromata. He had made careful and repeated search for the nerve fibers without finding them.

EXPOSURE TO THE SUN AS AN ETIOLOGICAL FACTOR IN ALOPECIA.

DR. GEORGE F. HARDING, of Boston, said that his deductions from the observations of 312 cases of alopecia in young people between the ages of twelve and twenty years would indicate that exposure to the sun was harmful rather than beneficial to the hair and scalp. These patients were seen in private practice during the past four years, and all of them had been for a year or more going in the open without head covering. The exposure in the majority of the cases occurred in the summer. Over two hundred spent their summers at the seashore, and in these the symptoms were the most pronounced. A large proportion (293) were blondes; this might have been merely a coincidence. On the other hand, it might be accounted for under the old theory that persons and animals with dark hair and skin were less sensitive to the sun's rays than blondes. The fact that light hair was, as a rule, much finer and delicate than dark might also be taken into consideration. The symptoms in these cases were quite constant, but varied in degree with the amount of exposure which had been undergone, and somewhat with the individual. The hair was dry, lusterless and faded; there was an evident lack of sebaceous secretion, with itching. The alopecia, as a rule, showed itself in those cases of but one season's exposure about a month or six weeks after the return to the city, and responded quite readily to treatment. In those who had had several seasons of exposure without intervening treatment, the fall had been continuous, and baldness was often marked. Those cases did not respond well to treatment, and the prognosis was decidedly unfavorable for a good growth of hair.

DR. WILLIAM A. PUSEY, of Chicago, said that several years ago, reasoning from the analogy of the x-ray, he was led to question the wisdom of exposing the tender and sparse scalps of many people to sunlight. The analogy was very close between the highly actinic rays of the sun and x-rays, and there was no doubt that we could produce baldness by the latter.

DR. JAMES NEVINS HYDE, of Chicago, said we knew that the x-ray and electricity might prove to be either most damaging or most beneficent agents. It depended largely on the dosage, and in the matter of the effect of sunlight in producing either hirsuties or alopecia, probably the racial element had much to do with it.

DR. JAY FRANK SCHAMBERG, of Philadelphia, speaking of the superior hair growth of negroes living under primitive conditions, said the fact must be borne in mind that there were other factors besides light which influenced their hair vitality. Indoor life, excessive eating, complex social burdens and mental activity all tended to lessen tissue vitality, and these factors were absent in negroes, Esquimaux and Indians living under primeval conditions.

DR. LOUIS A. DUHRING, of Philadelphia, thought

this was an opportune time for the profession to direct attention to the injurious effect of long-continued sunlight upon the scalp and hair, with the hope that fewer young people would unnecessarily expose themselves in this way.

General Discussion on Vaccine Therapy.

VACCINE THERAPY AS APPLIED TO CUTANEOUS DISEASES.

Dr. T. Caspar Gilchrist, of Baltimore, opened the discussion with a paper on this subject, in which he confined himself to the results of his own experience with the use of vaccines in the treatment of cutaneous diseases at the Johns Hopkins Dispensary and in private practice during the last three and one-half years. Over three hundred cases had been treated. As far as vaccine therapy was concerned in the treatment of cutaneous affections, Dr. Gilchrist said his experience might be summarized as follows: He had found it to be a distinctly valuable adjunct to our therapeutics. The staphylococcus albus vaccine was of undoubted value in the treatment of all pustular affections of the skin, but especially, in his experience, in the treatment of relapsing furunculosis, staphylococcic dermatitis, sycosis non-parasitica, in certain forms of eczema, in pustular rosacea and in acne when the disease was largely secondarily infected with the staphylococcus albus. He had also found the vaccines to be of value in the treatment of erythema multiforme, especially of the relapsing bullous type, and in rosacea where the flushings were decreased by the vaccine therapy. It was also helpful in dermatitis herpetiformis and pityriasis rosea, so much so that he would recommend vaccine therapy to be tried when the disease did not yield to the usual method of treatment. Bacillus acne vaccine he had found to be of great value, especially in the treatment of those chronic nodular relapsing types of acne vulgaris, and it had proved to be in his hands in a great many cases a curative agent.

BACTERIOTHERAPY IN CERTAIN DISEASES OF THE SKIN.

Dr. Martin F. Engman, of St. Louis, discussed this phase of the subject, and presented the following conclusions: (1) The dose of all forms of vaccines should be at first small. Doses of bacterial suspensions were, of course, approximate. (2) Small, continuous doses were best. (3) Increasing the dose was frequently risky. (4) Stock suspensions they had found very reliable and could be used in most instances. (5) Autogenous vaccines were indicated when stock suspensions failed. (6) Clinical indications alone had guided them in their latest and best results. (7) The opsonic index had proved to be unreliable and impracticable, and was not necessary. (8) The failure to obtain results in vaccine therapy might be due to faulty technic. (9) Vaccine therapy would fail in a certain percentage of cases. (10) Vaccine therapy was indicated in diseases of the skin due to a specific micro-organism. (11) In vaccine therapy we had at last a reliable beneficial agent in combating the deeper and more virulent staphylococcic infections of the skin.

VACCINE THERAPY IN THE TREATMENT OF DISEASES OF THE SKIN AT THE MASSACHUSETTS GENERAL HOSPITAL.

By Drs. Harvey P. Towle and George P. Lingenfelter, of Boston. The authors stated that before any new method in medicine or surgery could attain an assured position, it must have passed successfully through an evolutionary period of longer or shorter duration. But a small percentage survived the ordeal, and almost none could pass through unchanged, and this, it seemed, would be the case with the theory of vaccine therapy. It would undoubtedly survive, but it had already undergone very considerable modifications. The great mass of data resulting from the indiscriminate experiments during the first stage of enthusiasm was now sifted, and it began to be realized that the method had decided limitations and was by no means suitable for every case. This was the first step toward a fuller understanding. The cases to be treated by vaccines were now selected with greater care, and the authors felt justified in assuming that while vaccine therapy was undoubtedly a step in the right direction, the results obtained, considered as a whole and from all points of view, were not sufficiently superior to recommend the complete abandonment of the older, well-tried methods. The results seemed to show rather that we should avail ourselves of this new therapeutic agent as a powerful adjuvant to other methods rather than as a specific. It might be that in the future our knowledge of the exact meaning of the vaccine action would be sufficiently enlarged to enable us to advance still further along the line in vaccine therapy.

Dr. Francis J. Shepherd, of Montreal, spoke of the work of one of his assistants with this method, whose results with the vaccine treatment were brilliant in acne, especially in the superficial forms. He also had obtained excellent results in furunculosis and in the treatment of carbuncles. In some of the deeper forms of acne, the treatment was not satisfactory.

Dr. H. W. Stelwagon, of Philadelphia, said that, before hearing these valuable papers, he had about reached the conclusion, both from his own observations and from the work of other investigators, that the enthusiasm as to the vaccine therapy was on the decline. Nevertheless, in view of the brilliant results of vaccine therapy, as indicated in the papers just read, he felt it his duty to take up the method again experimentally.

Dr. William T. Corlett, of Cleveland, said that vaccine therapy was new, and, like many other new modes of treatment, it was liable at first to be misused and misjudged, but that eventually it would find its proper place when its beneficial effects would be better appreciated. In acne vulgaris, some cases under his observation had been treated very successfully by the vaccines, including some that had resisted other forms of treatment. In sycosis vulgaris he thought that the vaccines were especially indicated.

Dr. S. Pollitzer, of New York, said he held very much the same position on this subject as Drs. Hartzell and Stelwagon. Practically, everything was still to be proven. His principal objection to the evidence presented by the readers of the papers was fundamental; they had not employed vaccine therapy in the sense in which that term was ordinarily used. We understood by vaccine therapy the introduction into the system of bacillary substances derived from the dead bodies of the organisms that produced the disease, with the expectation of curing the disease by stimulating phagocytosis or opsonic activity.

Dr. William A. Pusey, of Chicago, said it was extremely difficult to judge of the value of any therapeutic measure in the diseases to which the vaccine therapy was chiefly limited, and the great value of these papers lay in their collation of a large number of observations by expert critical observers.

Dr. Randolph B. Carmichael, of Washington, D. C., said he recently saw two very aggravated cases of sycosis in which the autogenous vaccines had been used with not very favorable results.

Dr. Jay Frank Schamberg, of Philadelphia, said it should not be demanded that vaccine therapy, in order to be accorded an established place in our system of therapeutics, should alone and of itself cure the various conditions for which it was applied. It should

merely be required that it effected results, either alone or conjoined with other remedies, that were distinctly superior to those obtained by other means.

DR. OLIVER S. ORMSBY, of Chicago, said that for the past few years they had used the staphylococcus albus stock vaccines in large doses, but with rather disappointing results. More recently, however, they had carried on their work almost exclusively with the autogenous vaccines in smaller doses, and their results had been much better, although not as brilliant as they had hoped for. He thought that with an improved technic there was no question about the value of the treatment.

DR. E. WOOD RUGGLES, of Rochester, N. Y., said that his work with vaccine therapy was limited to the autogenous vaccines. In furunculosis, his results with the treatment had been good, so far as subsidence of pustular lesions was concerned, but the underlying acne (comedones and oily skin) was little if at all affected. He had used only staphylococcus vaccine.

DR. HOWARD FOX, of New York, said that his results with the vaccine therapy during the past year had been rather disappointing. From his own experience, which was limited, and from what he had learned from others, he had been led to the conclusion that vaccine therapy in dermatology had a very limited field. In furunculosis, his results with the staphylococcus vaccine had been fairly good, while in acne indurata they had been very disappointing.

PELLAGRA IN OHIO.

By DR. WILLIAM T. CORLETT and DR. OSCAR T. SCHULTZ, of Cleveland. The authors stated that, following the awakening that pellagra existed in this country, many pseudo-cases were brought to the attention of experts in cutaneous medicine. The paper then gave a brief history of one of these cases seen in Ohio, where the patient was supposed to have contracted the disease from "corn smut." In the opinion of one of the writers, this case was nothing more than an obstinate form of eczema. An investigation of supposed epidemics of some unknown disease of the skin in two of the state hospitals for the insane in Ohio revealed nothing unusual. All doubt as to the presence of pellagra in this country was removed, however, on visiting the hospital for the insane at Peoria, Ill. The authors then gave in detail the history of the first case of this disease recognized in Ohio, with photographs of the skin lesions, post-mortem findings and histology. It was thought, in conclusion, that the disease, while not wholly confined to certain regions of this country, yet its limitation was fairly well defined and that from the testimony of those who had seen most of the affection in this country, it was not entirely new.

DR. JAMES W. BABCOCK, superintendent of the State Hospital for the Insane at Columbia, S. C., and president of the National Pellagra Congress, said he understood that there was considerable skepticism in regard to the existence of pellagra in this country, and it was only those who had served in public institutions, particularly in the southern states, and who had been face to face with this condition for years, who could comprehend the importance of having more light shed on this mysterious malady. A year ago a conservative estimate of the number of pellagrins in the United States placed the number at 1,500; recently, the figures had been gone over, and it now appeared that the disease had been recognized in twenty-seven or twenty-eight states. Cases had been reported in two hospitals in Illinois, and subsequently in a third, and it had been shown beyond the shadow of a doubt that the disease existed in some of the western states, including California, so that we now had come to the conclusion that it had a very widespread distribution. Dr. Babcock said that from personal investigation and inquiry he was satisfied that pellagra had existed in South Carolina for nineteen years, at least, and there were traditions of cases that went back as far as 1870. In reply to a question as to the mortality of the disease, the speaker said that in one insane asylum for white people in the South where they had observed the disease since 1896, they had 27 cases, with 18 deaths. The mortality, according to different observers in the South, varied anywhere from 40% to 70%.

DR. JAMES NEVINS HYDE, of Chicago, showed an original copy of a volume entitled "Historia Natural Y Medica," by Dr. Gaspar Casal, which was published in Madrid in 1762, and which, so far as was known, was the first contribution to the subject of pellagra. Dr. Samuel Sherwell, of Brooklyn, was properly credited with having made the first contribution on this subject, to the American Dermatological Association. This was in 1882.

DR. HOWARD FOX, of New York, referred to his work in experimental serum therapy in pellagra, and regretted that he was not yet prepared to present a paper on that subject.

DR. S. SHERWELL, of Brooklyn, said the case referred to by Dr. Hyde was published in the *Journal for Cutaneous and Venereal Diseases*, in February, 1883. The patient was an Italian sailor, with both subjective and objective symptoms, forming together a classical picture of the disease. Two years later a similar case presented itself at his clinic, almost or quite identical to the first. Both cases ended fatally.

DR. H. W. STELWAGON, of Philadelphia, said that several European observers who had studied this disease had made the observation that pellagra had occurred in persons who had never eaten corn. Among this number was Kaposi, and, he believed, Besnier also.

DR. SHERWELL thought that the fungus or parasite to which pellagra had been attributed might occur in all cereals analogous to corn, such as rye, etc.

DR. M. B. HARTZELL, of Philadelphia, reported a case of apparently typical pellagra occurring in a subject who had never been outside the state of Pennsylvania, and who, so far as could be ascertained, had never eaten Indian corn.

DR. LOUIS A. DUHRING, of Philadelphia, believed that the causative factor of pellagra was distinctly internal, and probably of a toxic nature.

DR. WILLIAM A. PUSEY, of Chicago, speaking of the exclusion of corn from the diet, said that when it came to the statement that a patient in this country had never eaten Indian corn, the reliability of such a statement could be seriously questioned. The statement was analogous to the contention of Jonathan Hutchinson in regard to the relation between leprosy and eating fish; Hutchinson was always prepared to prove that any one had eaten fish. Dr. Pusey said that while we had made an important advance in recognizing the presence of pellagra in this country, he was inclined to believe that the diagnosis was now being overworked. Pellagra was not a condition in which we could make as satisfactory a diagnosis as we could in tuberculosis or syphilis. The diagnosis rested on a trial of symptoms — psychical, gastro-intestinal and cutaneous. It was essentially a picture of auto-intoxication, such as we met with in gastro-intestinal disturbances, and he believed that many of the cases of so-called pellagra might well be questioned as to the accuracy of the diagnosis.

PRURIGO, AND THE PAPULE WITH THE URTICARIAL BASIS.

By DR. O. H. HOLDER, of New York: This paper embraced an anatomical study of the pale papule of prurigo.

SOME PROBLEMS IN METABOLISM OCCURRING IN PATIENTS WITH CERTAIN DISEASES OF THE SKIN.

Dr. L. Duncan Bulkley, of New York, said that faulty metabolism was recognized as a cause of many diseases; it might affect all the body tissues, and it was natural to expect that the skin participated. While definite and specific statements could not yet be made as to the exact and particular metabolic derangements belonging to various diseases of the skin, there were abundant clinical evidences that the cellular derangements which constituted the bottom fact in skin lesions had an intimate connection with and dependence upon metabolic errors. The urine, coming directly from the arterial blood, furnished a most suitable indication of the condition of the blood, as it had been prepared through metabolism; consequently, repeated, careful volumetric analyses of its constituents furnished the most certain method of determining the performances of anabolism and katabolism in the tissues.

Dr. Louis A. Duhring, of Philadephia, said that this subject of metabolism in relation to diseases of the skin had interested him for many years, and he had long since ceased to study and treat diseases of the skin — as he did years ago — from the standpoint of the lesions alone. If we wished to permanently cure many of the skin lesions, we must study the patient and conditions within the body. He had long been dissatisfied with the usual local treatment in a large number of chronic inflammatory diseases of the skin.

Dr. King Smith, of Toronto, said that Dr. Sims Wood, of London, England, in an address before the students of the Toronto University, had laid great stress upon the close relationship between the men who worked in the laboratory and the clinicians.

Dr. M. B. Hartzell, of Philadelphia, asked Dr. Bulkley if he controlled the results he obtained by comparing them with the urinary findings in those who had no skin eruptions. The speaker said he was convinced that such a comparison would show just as wide variations in one as in the other.

Dr. S. Pollitzer, of New York, said that while quantitative analyses of the urine might be very useful, they did not constitute studies in metabolism. In fact, they were utterly worthless for that purpose unless at the same time the diet of the patient was controlled, and the intake and output compared.

Dr. Bulkley, in closing, reiterated his belief that faulty metabolism was an important factor in connection with diseases of the skin.

SECONDARY ECZEMA.

Dr. John A. Fordyce, of New York, in his paper on this subject, stated that, in observing a large number of cases of dermatitis in hospital and dispensary practice, he had been struck by the frequency with which forms of skin infection which were usually diagnosed as eczema had been secondary to some antecedent lesion or disease of the skin, such as scabies, wounds or traumatisms which had become infected, abscesses, furuncles, intertrigos, sinuses left after operations on bones, etc.; in other words, the percentage of eczemas in which some antecedent pathological condition could not be determined seemed to be in the minority. From an extensive experience with cases of eczematoid dermatitis in which a history of antecedent pus infection was obtained, the conviction had come to him that irritation of the skin produced by discharges from abscesses, sinuses, ulcers and other pus-secreting surfaces was the true basis of these phenomena. This irritation might be followed by eruptions of most diverse forms, such as a dry scaling dermatitis or large moist areas, or a combination of dry scaling lesions and moist and crusted ones. Sometimes the picture was that of an acute vesicular eczema, and could not be distinguished from the usual forms of eczema which had been attributed to some internal disturbance. In all or most of these forms the affection was distinctly autoinoculable, and in many a condition of chronic eczema or dermatitis persisted for months or years. There might or might not be relapses; in many cases recovery was permanent. On the other hand, with a lowered resistance to pus infection, recurrences took place as furuncles and abscesses, with a subsequent eczema. One of the most prominent features in many patients with eczema was the increased susceptibility which their skin presented either from the beginning, or which developed as the process progressed. It was this heightened susceptibility which led to relapses, as was often seen in workers in chemical laboratories, in whom the vapor of formaldehyde provoked forms of dermatitis of the nature of eczema. The same condition was seen in individuals who had once developed dermatitis from poison ivy or other local irritant; after one attack, many of these people were increasingly susceptible to the specific irritant, and it was quite possible in these cases to attribute the frequent recurrences to a state of anaphylaxis. Individuals who showed such an increased susceptibility to irritants might perhaps be sensitized to the chemical products of pus organisms, just as patients with tuberculosis might be sensitized to tuberculin. Assuming, therefore, that we might have a state of hypersusceptibility to irritants which might be present either from birth or acquired from some change in the biological properties of the blood serum due to various affections, we could readily understand how irritants of the most varied kind might evoke a dermatitis. These serological changes might a also explain the simultaneous or successive occurrence of skin and mucous membrane affections in patients who had become sensitized with an irritant, in the one case acting on the neurovascular apparatus of the skin, and in the other on the mucosa.

Dr. Martin F. Engman, of St. Louis, said that Dr. Fordyce, in his paper, had opened up a field which showed the way to a great deal of valuable work.

Dr. M. B. Hartzell said he was quite convinced that in a certain number of cases there was a local sensitizing of the skin. We found certain eruptions in certain localities again and again in certain individuals who at first showed no such sensitiveness to such irritating agents.

A FATAL CASE OF BULLOUS DERMATITIS.

Dr. S. Pollitzer reported this case, which he summarized as follows: The patient was a middle-aged man, of good habits, in good health, except for a chronic diffuse nephritis which apparently gave no trouble. He was attacked with a dermatitis that had the character of a fine, scaling, pruritic erythrodermia and that rapidly spread over the entire integument. Its development was in some places preceded or accompanied by a severe edema, which subsequently subsided, but a moderate edema of the entire surface persisted for two weeks. Ten days after the appearance of the scaling red areas, crops of large bullæ appeared in various parts of the body, but mainly on the extremities and the buttocks. The development of fresh blisters, in general smaller than at first, continued in greater or less number throughout the course of the illness and the skin became diffusely pigmented. Temperatures following a septic curve up to about 104 developed, the patient became delirious and fell into a typhoidal state which terminated after a fortnight in coma and death, the whole course of the illness lasting about forty days. The blood showed at first an extra-

ordinary eosinophilia, which later assumed moderate proportions. Blood cultures, cultures from the blister serum and inoculations of the latter were negative, as was also the examination of the illumined dark field. The post-mortem examination threw no light on the case. As to the diagnosis of this remarkable case, it might be said that we were certainly not dealing with a pemphigus, as modern usage limited that term to a disease which was primarily bullous. The acute form of pemphigus, which alone could come under consideration in this connection, might be excluded by the absence of any infected wound, and, above all, by the preliminary diffuse scaling.

DR. J. A. FORDYCE, of New York, spoke of a case similar to the one reported by Dr. Pollitzer, excepting that there was no history of any antecedent eruption. The case also ended fatally. The etiological factor in these cases, the speaker said, was still unknown. It was perhaps some obscure proteid or a chemical product.

DR. DUHRING said it seemed to him that whatever the cutaneous lesion might be at the outset, the condition often or generally developed into what might properly be called pemphigus, and he could see no objection to classifying it as a case of pemphigus malignus.

DR. JAMES NEVINS HYDE, of Chicago, said the case reported by Dr. Pollitzer was a commentary upon our occasional impotence and lack of knowledge. Here we had an interesting and fatal case reported under a title which referred to a condition of the skin merely, and yet the symptoms showed that we were obviously confronted with some toxic process which profoundly influenced the entire economy, and of which the skin lesions were simply the superficial evidence of the deeper trouble.

DR. POLLITZER, in closing, said that in pemphigus malignus or acutus to which Dr. Duhring had referred, there was usually a history or preceding injury, followed either immediately or in the course of a few days by an acute septic condition, with the formation of bullous lesions on the skin. There was no history or evidence of such a condition in this case.

Book Reviews.

The Sexual Life of Woman in its Physiological, Pathological and Hygienic Aspects. By E. HEINRICH KISCH, M.D., Professor of the German Medical Faculty of the University of Prague; Physician to the Hospital and Spa of Marienbad; Member of the Board of Health, etc. Only authorized translation into the English language from the German by M. EDEN PAUL, M.D. With 97 illustrations in the text. New York: Rebman Company. 1910.

Those who are familiar with Kisch's previous writings on this subject, beginning with his "Climacteric Period in Women," published in 1874, will welcome this assembling and analysis of the opinions of a wide range of authorities, and also of the views developed by the accomplished author's lifetime of investigations in an important field. On the other hand, those who read the author for the first time will find this book a mine of information on all matters pertaining to the sexual function in woman.

The subject-matter — 667 large pages — is divided into three parts: the onset of menstruation — the menarche or puberty; the culmination of sexual activity — the menacme; and the cessation of menstruation — the menopause. A detailed description is given of the normal and morbid anatomy of the female genital organs, also of their physiology and their deranged function under the different conditions of disease. There are numerous statistical tables from authors of note, although the references are seldom given in full; ninety-seven illustrations, showing well the points made by the author, and a fairly good index.

The translation from the German has been well done, although the use of such words as "sacrache" for pain in the region of the sacrum, and the occasional uncertainty of meaning because of the omission of commas, offends the student of English in several places. The many directions for treatment scattered throughout the work should be of assistance to the practitioner. Altogether, this may be regarded as one of the important books of the time.

A Manual of Operative Surgery. By SIR FREDERICK TREVES, Bart., G.C.V.O., C.B., LL.D., F.R.C.S., Sergeant-Surgeon to H. M. the King; Surgeon-in-Ordinary to H. R. H. the Prince of Wales; Consulting Surgeon to the London Hospital; and JONATHAN HUTCHINSON, F.R.C.S., Surgeon to the London Hospital. New (third) edition, revised and rewritten. In two octavo volumes. Volume II. Pp. 820, with 302 engravings and 8 full-page plates. Philadelphia and New York: Lea & Febiger. 1910.

This second volume of Treves' "Surgery" is as attractive in appearance as Volume I, and deals with a variety of topics in an entertaining and instructive fashion, but it is fragmentary. It does not carry out the promise of Volume I. In that it is disappointing. The writers deal with operations on the head, neck and spine, with operations on the thorax and breast, on the blood vessels and nerves, on tendons and muscles, on bones and joints and with amputations. With amputations they are especially concerned, with the concern of surgeons of the old school. In this book of 809 pages, 201 pages, or a quarter of the whole volume, are devoted to amputations. Consequently, there are many things which appeal to well-read, modern surgeons which are lacking, and the index of the book is grievously disappointing. In it we fail to find such words as *hypophysis*, as *cerebral decompression*, as *pituitary body*, as *hyperthyroidism*. The little article on Graves' disease is so trifling as to be negligable; in the chapter on surgery of the thorax, *differential pressure* is not mentioned; and in the description of amputation of the whole upper extremity, —a matter with which the authors especially concern themselves, — no proper comment is made on methods of controlling shock and hemorrhage.

Of such a nature are the faults of this book. Nevertheless, the book is by no means to be con-

demned. It is well written, the topics are presented attractively, and the comments of the writers leave an impression on the mind of the reader. In other words, we believe it is a book which the well-informed general surgical reader will peruse with interest. It is not a book to which the overworked clinical surgeon will turn for information on special points of technic.

Dislocations and Joint Fractures. By Frederic J. Cotton, A.M., M.D., First Assistant Surgeon to the Boston City Hospital; Assistant Professor of Clinical Surgery in Tufts College Medical School, Boston. With 1,201 illustrations, 830 from drawings by the author. Philadelphia and London: W. B. Saunders Company. 1910.

In this unusual book of 638 pages Cotton has reanimated one of the dullest topics in all surgery. By that work he has done a very great service. Not only has he written the book himself, but he has illustrated it, so that one sees vitalized the victims of the injuries which he describes. The work is delightful, spirited, scholarly and original, and is not only a book of reference, but a book for casual reading. It brings the subject of dislocations and joint-fractures up to date, a feat long neglected.

Here are some of his own remarks on his work: "Dislocations do not present themselves to us as such, but rather as *injuries to* or *near* the *joints*. Dislocations neatly and academically classified — considered as of settled diagnosis and irrespective of complications — could be considered, with all the reduction schemes thrown in, in but few pages. *Injuries to and about joints*, on the other hand, constitute one of the most doubtful fields of surgery, a field strewn with wrecks, — the products of mistakes and of unavoidable difficulties, prolific in discontent and in resultant actions at law — actions based only too often on unavoidable uncertainty or error. . . . This dangerous field has been rather inadequately surveyed. . . . There is bound to be a broadening recognition of the fact that *each fracture is a mechanical problem in itself*, so far, at least, as reduction is concerned. . . . Our duty is *to obtain in the given case the best result obtainable in this case, by whatever means are at hand*, often irrespective of traditional methods. . . . I can see that the day is past when we may defend ourselves by abjectly falling back on what the eminent Dr. X. said in the last century."

Such stimulating reflections, taken from the author's introduction, indicate the scope and nature of his work. He is an independent writer, who does his own thinking; he neither ties up to nor discards x-rays; he appreciates the work of others; he is fertile in suggestions regarding treatment; he approves of massage; he operates upon simple fractures when necessary; he gives excellent advice regarding the possibilities of actions at law; and he fills his book with vital, new and instructive pictures. Surgeons, house surgeons and general practitioners should own and study this volume.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 22, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

THE QUESTION OF INFANT MORTALITY.

It has long been recognized and no doubt will long continue to be the fact that the mortality of childhood is far greater than that of any other period of life. Many of the reasons for this are sufficiently obvious, but the more the subject is investigated the more apparent it becomes that a large proportion of these deaths are unnecessary, and under proper conditions of hygienic living could in great part be prevented. A recent publication of the Department of Commerce and Labor makes the statement that of the total number of 732,538 deaths in 1909, 196,534 were of children under five years of age and 140,057 of infants under one year of age. In other words, approximately one death out of every five in that year was of a child under one year old. Of these deaths the mortality is somewhat higher in the cities than in rural districts. In New York state, with a mortality of 12,942 in July, 3,486 deaths occurred under one year of age. During this month there were upwards of 2,000 deaths from enteritis alone. Of the total number of deaths under one year, 64% were in New York City.

Efforts are being made, both by individuals and collectively, to study the exact causes of this great mortality, and also to devise practical means for its reduction. Among the organizations which are doing excellent work in this regard may be mentioned the American Association for the Study and Prevention of Infant Mortality, the object of which is primarily to co-ordinate all sanitary agencies for the purpose of reducing the number of preventable deaths in infancy. The report before us suggests that in order that such a comprehensive plan may be carried out, it is essential that reliable statistics of infant mor-

tality should as soon as possible be available for the entire United States. Inasmuch as the deaths under consideration are chiefly those under one year of age, it becomes extremely important that births should be much more accurately registered than is at present the case.

Dr. Arthur Newsholme has made an important contribution to the subject by his recent report on infant and child mortality published in England. Among other things, he draws attention to the fact that "infant mortality is the most sensitive index we possess of social welfare and of sanitary administration, especially under urban conditions." It appears that the districts suffering most from a heavy child mortality continue to have higher death-rates among adults than the districts where the infant mortality is low. The observation is furthermore of interest that the study of the death-rate of England and Wales during the last fifty years leaves it doubtful whether any greater weeding-out process is exercised by a heavier than by a lighter infant mortality. If such effect exists, it is counterbalanced by the influence exerted by the environment to which children are exposed in districts of high infant mortality. Dr. Newsholme, therefore, feels justified in making the following statement: "It is strictly correct to say that a high infant mortality implies a high prevalence of the conditions which determine national inferiority."

Mr. John Ritchie, Jr., has made a careful study of the conditions underlying infant mortality as they exist in Boston, his paper being originally published in the Boston *Transcript* for March 30, 1910. Mr. Ritchie points out certain fallacies and difficulties in the way of estimating the mortality, particularly in view of the laxity in the notification of births. It appears that Boston is far ahead of many of its sister cities in its system of vital statistics, since approximately 95% of its births are recorded and deaths actually known. From this it follows that the infant mortality may be very closely determined, as contrasted, for example, with a city like Chicago, where it is said that not more than 65% of newborn babies are registered. With Baltimore the percentage falls as low as 45%. The comparison between American cities, therefore, as to infants' deaths must be misleading and inexact. So far as may be determined with the evidence at hand, Boston stands well among American cities in respect to its infant mortality.

It is evident, however, that, before any exact statistics may be gained, it will be necessary that various parts of the country shall adopt, if not a uniform, at least an approximately exact, method of registration of births and deaths. With our growing knowledge of the prophylaxis of disease in general, and of infantile disease in particular, it is not to be questioned that before many years have passed a creditable showing will be made in respect to deaths among small children. In the meantime, co-operation is desirable between civic and scientific bodies to the end that the investigation be most searching in its character and comprehensive in its scope.

THE ETIOLOGY OF BERIBERI.

THE excellent medical work being done in the Philippines is illustrated by a series of articles in a recent number of the *Philippine Journal of Science* on beriberi. This disease, prevalent particularly in the East, but also not infrequently appearing in sporadic form in more western countries, has long evaded a determination of its cause. It now appears to be somewhat conclusively shown, as verified by a number of observers, that the disease is due to the eating of white rice in which the polishing process has been carried out. The suggestion of this relationship was first by Braddon and later confirmed by various other investigators. For some time, however, after the discovery that white rice produced the disease it remained obscure by what mechanism this was brought about. The various theories entertained from time to time do not here concern us. In the process of these preliminary researches attention was drawn to the possibility of an explanation on the hypothesis of a defect in nutrition. Fowls fed on rice were found to be sensitive to different varieties. Further study along this line with rices known to have been associated with epidemics of beriberi proved that a certain reaction in fowls might be taken as an indicator of the beriberi-producing power of a given rice. It is the belief of Fraser and Stanton that the polyneuritis of fowls is entirely analogous to beriberi in man and, therefore, that the experiments with rice feeding may be regarded as essentially conclusive. It appears from various evidence that Siam rice is more potent in producing beriberi, for example, than Rangoon rice. It was a natural step to investigate chemically the rice granule and also to study the effect produced by its preparation for the market. As a final result of these investigations it has been shown that beriberi is a disorder of metabolism and certainly in the Philippines is associated with a diet of which white rice is the principal

constituent. White rice as produced in the mills is deficient in some substance or substances essential to the normal metabolism of nerve tissue, and these essential substances appear in superabundant amount in the polishings from the rice. The interesting fact is, therefore, adduced, that the prevention of beriberi in the Philippines will be accomplished by substituting for the ordinary commercial white rice a rice in which the polishing process has been omitted or carried out to slight degree, or by the addition to an ordinary white rice diet of articles of food rich in the substances deficient in the prepared white rice. The polishings from white rice might, for example, be so used. Parboiled rice also seems to accomplish a like result. The exact nature of the constituents necessary to the metabolism of the nerve tissue cannot as yet be definitely stated, but the important practical fact remains that the covering of rice ordinarily removed in process of cleaning is essential for the prevention of beriberi, if rice be a staple diet.

Details of this extraordinary scientific discovery are given in several articles appearing in the same number of the *Journal*, together with an instructive series of photographs of fowls illustrating their appearance when suffering from the polyneuritis induced by a diet of cleaned white rice. It is presumably not to be supposed that the occasional epidemics among fowl in this country at times presumed to be poliomyelitis are beriberi, but the suggestion lies near that the feeding of the fowls affected with this paralyzing disease may well be investigated in the light of the information derived from the experiments to which we have alluded. If the foregoing theory of the causation of beriberi is correct, and the evidence seems cumulative that it is, there can be little question that another serious menace to life has been removed and that this dreaded disease of eastern countries will be placed in the growing category of those regarded as entirely preventable.

MEDICAL NOTES.

Officers of American Electro-Therapeutic Association. — The American Electro-Therapeutic Association held its twentieth annual convention at Saratoga Springs, N. Y., Sept. 13, 14 and 15. The following officers were elected for the ensuing year: President, Dr. Frederick de Kraft, New York; Vice-Presidents, Drs. F. Howard Humphris, of London, and Frank B. Granger, of Boston; Treasurer, Dr. Emil Heuel, New York; Secretary, Dr. J. Willard Travell, New York; Registrar, Dr. Frederick M. Law, New York; Trustees for three years, Drs. Charles R. Dickson, of Toronto, and Thomas D. Crothers, of Hartford, Conn.

Far Eastern Association of Tropical Medicine.— According to the quarterly report of the Bureau of Health of the Philippine Islands, the first biennial meeting of the Far Eastern Association of Tropical Medicine was held in the city of Manila from March 5 to March 12, 1910, inclusive, and in Baguio on the 13th and 14th of March. Delegates were present from Japan, China, Hongkong, Straits Settlements, India, Siam, Java and other Far Eastern tropical countries. The character of the papers read at the congress was of a very high order and much original scientific work was presented, some of which will no doubt rank among the epoch-making announcements in medicine during the present century.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Sept. 20, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 12, typhoid fever 11, measles 3, smallpox 0, tuberculosis 60.

The death-rate of the reported deaths for the week ending Sept. 20, 1910, was 17.50.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Sept. 17, 1910, was 219, against 177 the corresponding week of last year, showing an increase of 42 deaths, and making the death-rate for the week, 17.03. Of this number 108 were males and 111 were females; 208 were white and 11 colored; 158 were born in the United States, 57 in foreign countries and 4 unknown; 42 were of American parentage, 151 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 24 cases and 3 deaths; scarlatina, 10 cases and 0 deaths; typhoid fever, 18 cases and 4 deaths; measles, 3 cases and 0 deaths; tuberculosis, 50 cases and 26 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 20, whooping cough 2, heart disease 22, bronchitis 2. There were 15 deaths from violent causes. The number of children who died under one year was 67; the number under five years, 85. The number of persons who died over sixty

years of age was 64. The deaths in public institutions were 92. Cerebrospinal meningitis, 4 cases and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 2 cases and 2 deaths. Diphtheria, 1 death. Scarlet fever, 4 cases.

Deducting deaths of non-residents, the total is 191 and the death-rate is then 14.85.

DIPHTHERIA IN WESTFIELD, MASS. — It is announced that the appearance of diphtheria in the Polish section of Westfield has lead the health authorities to postpone the opening of the largest schools. Thirty-five cases of the disease and five deaths have occurred in one week.

A CASE OF HOOKWORM DISEASE IN BOSTON. — A case of hookworm disease in a native of the Cape Verde Islands is under treatment at the Carney Hospital, South Boston. The patient reached this country recently and landed in Providence after a sea voyage from the tropics.

THE POLIOMYELITIS SITUATION. — It is reported that the Middletown, Conn., Board of Education has decided to close the public schools for an indefinite period owing to a recent outbreak of poliomyelitis in that city. In nine days fourteen cases were reported, with three deaths, two of them in adult school girls. The situation in regard to poliomyelitis in Rhode Island, particularly in Providence, has been disturbing for some weeks past. The death has just been reported of a boy of sixteen whose illness led to the closing of the Arlington Grammar School at Cranston. The epidemic at Springfield, Mass., has apparently spent itself. Very few cases have been reported from Boston or its immediate neighborhood.

NEW YORK.

A CENTENARIAN. — Mrs. Antoinette Boeram died at her home in New York City on Sept. 9, at the age of one hundred and two years. She was born at Denton, Orange County, N. J., the year that President Madison was elected, and was the daughter of Dr. Nathaniel Elmer, Jr. She was twice married, and is survived by one daughter, eight grandchildren and six great-grandchildren. One of Mrs. Boeram's daughters died only a week before her own death.

BEQUESTS. — St. Luke's Hospital, New York, is to receive half the estate of the late Mrs. Mary Nevins Mayo, widow of Dr. Mayo, of New York, valued at $100,000, on the death of her nephew, Russell N. Bellows, named as residuary legatee under the will. By the will of Mrs. Charlotte D. Ferry, who died recently at Litchfield, Conn., $3,000 is left to St. Luke's Hospital for the endowment of a free bed in the children's ward. Among the charitable bequests in the will of Mrs. Sarah Titus Zabriskie, of New York, who died recently at her summer residence at Newport, R. I., is one of $1,000 to St. Mary's Free Hospital for Children, New York.

QUARTERLY MORTALITY REPORT. — The condensed quarterly report of Bureau of Records of the City Health Department for the quarter ending June 30, 1910, has just been issued. The principal decreases from the average number of deaths in the corresponding quarters of the preceding five years are as follows: Pulmonary tuberculosis, 319; simple meningitis, 340; cerebrospinal meningitis, 285; apoplexy and softening of the brain, 380; pneumonia, 128; bronchopneumonia, 242; Bright's disease and acute nephritis, 125; violent deaths (suicide excepted), 150; deaths under five years, 758; deaths in tenement houses, 1,230. In no disease did the increase of deaths over the quinquennial average amount to 100; the largest being in cancer, 67.

BUILDING OF NEW YORK ACADEMY OF MEDICINE. — The New York Academy of Medicine has secured the purchase of two city lots adjoining its present quarters, with a view to ultimately increasing the size of its building and thus meet its growing needs, especially as regards accommodations for its great library. One of these lots, 20½ by 100 feet, is next its building on Forty-third Street, and the other, 25 by 100 feet, is directly back of this, with a frontage on Forty-fourth Street. The price of the one is $100,000 and of the other, $120,000. It has been decided to raise a mortgage upon the present building at 4½% to pay for the new lots, and at this rate it will cost $6,000 a year to pay interest and taxes upon this property until the mortgage is paid off by contributions, or the taxes are remitted when the Academy occupies it for its own use. The present lease of the building on the new Forty-third Street lot does not expire until 1916, but the Forty-fourth Street lot, on which there is an unoccupied two-story stable, will be used for stack and administration purposes as soon as there is sufficient money on hand with which to begin construction.

DEATH-RATE. — The death-rate in the city during the month of August showed a very marked

decrease from that of July. Not only was it remarkably low for this season of the year, but it was lower than in any previous month in 1910, and the lowest since September of last year. The rate was 14.91, as against 17.79 in July and 15.25 in August, 1909. The corrected rate, excluding non-residents and infants under one week old, was 14.14. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from measles declined from 13.25 in July to 7.25 in August; the weekly average from scarlet fever, from 9 to 2.75; from diphtheria and croup, from 26.5 to 19.75; from whooping cough, from 10.75 to 9.25; from epidemic cerebrospinal meningitis, from 5.5 to 4.5; from pulmonary tuberculosis, from 162.75 to 152.25; from pneumonia, from 49.75 to 47; from bronchopneumonia, from 65 to 49.75; from diarrheal diseases, from 399.25 to 268; from diarrheals in children under five years of age, from 376.5 to 255; from apoplexy and softening of the brain, from 17.25 to 14.25; from organic heart diseases, from 103.5 to 89.75; from appendicitis and typhlitis, from 17.75 to 12.5; from Bright's disease and acute nephritis, from 93 to 90.75; and from puerperal diseases, including septicemia, from 14 to 12.25. Among the few diseases in which there was an augmented mortality were the following: The weekly average of deaths from typhoid fever increased from 12 to 15.75; from acute bronchitis, from 9.75 to 11; from cancer, from 66.25 to 70.75; and from cirrhosis of the liver, from 18.5 to 23.5.

Epidemic Poliomyelitis. — Epidemic poliomyelitis has been added to the list of communicable diseases, the occurrence of which is required by the State Department of Health to be reported to local health officers, and by them to the department. The last *Monthly Bulletin* calls attention to the fact that fully 2,500 cases occurred in New York in 1907, the largest epidemic of the disease ever reported in the state, and goes on to say that while laboratory workers have recently demonstrated that infantile paralysis is an infectious disease caused by a specific organism, "the laboratory has not yet put us in possession of the essential facts as to how the disease enters the human body, or how to prevent or check its spread. The laboratory work must be supplemented by a field study. We need to classify the early symptoms and establish, if such there be, types of the disease; we need to investigate the conditions under which infection seems to occur, with a special inquiry as to the mode of entry of the virus into the body. The New York State Department of Health desires the co-operation of the physicians of the state in the making of such an investigation. Valuable work upon the same lines has already been done by the medical profession and the State Board of Health of Massachusetts, and for the sake of uniformity, and with a view to ease of comparative study, the New York State Department of Health is sending out to the health officers for distribution among the physicians of the state a duplicate of the blank used by the Massachusetts Board in its investigation. It is sincerely hoped that every physician in whose practise a case of infantile paralysis may occur will use this form and make as full a report as possible. With a view to the prevention of the disease, the State Department of Health expects that every case discovered will be quarantined. Some local boards of health have already passed an ordinance requiring a quarantine in this disease, and such action is approved by the department. The discharges from a patient (stools, urine and sputum) should be disinfected."

8. Pottenger describes two physical signs, easily elicited, which he has found very valuable in the early diagnosis of small apical lesions. They are lagging of the apex and spasm of the adjacent muscles. Lagging of an apex means that it is the seat of a pathological process. In testing for this sign, the examiner stands behind the patient with his thumbs placed on the supraspinous fossæ and his fingers down over the anterior chest wall. Muscular spasm is easily demonstrated by palpation. The writer asserts that rigidity of the neck muscles, the intercostals and the pectorals is as constant in early phthisis as abdominal rigidity is in acute abdominal conditions. [L. D. C.]

1. Lockwood briefly discusses the subject of fibroma, sarcoma and fibromyoma of the abdominal wall as to morbid anatomy, etiology, clinical history, diagnosis, surgical treatment and recurrence. He gives several short case histories.

3. Royle presents an elaborate paper endeavoring to show that in cases of cancer or blood disease there is, first, an abnormally large output of uric acid in the urine and an abnormally small amount of phosphates; second, that the uric acid phosphate ratio is always decreased in cancer, and that any ratio below 3 means that cancer is present. She presents this merely as a preliminary report.

2. Short presents a review of 40 cases of epithelioma of the lip. Of 23 cases in which the glands were not removed and in which only one operation was done, 14 are well one to nine years afterwards; of 6 cases in which palpable glands were removed, 3 died of recurrence. To summarise, in 20 patients with a growth on the lip less than one third of the lip in size, with no glands palpable, treated by local removal, only 3 died of recurrence; of 6 patients in which the growth and the palpable glands were removed, 3 died of a recurrence. He presents his results in tabular form. In view of these results, he is strongly of the opinion that this radical dissection of the whole lymphatic area should be done whether or not there are palpable glands present.

1. Bier, A. *On Local Anesthesia with Special Reference to Vein Anesthesia.*
2. Mackay, G. *The Causes and Prevention of Blindness.*
3. Haultain, F. W. N. *Some Practial Points in the Life-History of Uterine Fibromyomata.*

1. Bier discusses the development of local anesthesia with cocain, with special reference to Schleich's infiltration method. He urges the need of waiting as an essential to success; also that considerable amounts of the anesthetic be used if need be, stating that 80 to 120 ccm. of 5% novocain solution can be injected into an adult without danger. He discusses Braun's method and the perineural method. The greater part of his paper he devotes to a description of what he calls vein anesthesia. Complete ischemia of the part injected is of the greatest importance. He usually injects 100 ccm. in the lower limbs, 50 to 80 ccm. in the upper limbs, of a .5% isotonic novocain solution. Any large subcutaneous vein can be used for the injection. He goes into the details of technic, illustrating by means of diagrams, etc., the placing of bandages, insertion of canulæ, etc. He has used this method in 244 cases with but 5 failures.

12. Jacobsohn, L. *A Pepsin Composition of a Light Chrome Gelatin as the Background of a Biological Photographic Developing Media.*

2. Herxheimer reports on his results with Ehrlich's new arsenic compound in about 80 cases of syphilis. He compared the rapidity of the disappearance of symptoms and local reaction with calomel given subcutaneously or intramuscularly, and thinks that the arsenic compound acts better. He thinks it is contra-indicated in cases with cardiac weakness and any abnormality in sight and with purulent bronchitis; also in congenital syphilis of severe type. He does not use more than one injection, avoiding others, he says, for fear of anaphylaxis. It would seem that this is an important point in the advisability of using this drug, if it cannot be used more than once. This author, however, dismisses this phase of it with this single sentence.

6. Pels reports a case of alcoholic neuritis in which all the symptoms were on the sensory side. The differential diagnosis from tabes was extremely difficult. [C. F., Jr.]

9. MASUYAMA, M. *Clinical Knowledge of the Plague.*

2. Stierling examined the movement of ingesta in the large intestine of man by means of the x-ray, both in normal and pathological cases. He uses 20 gm. of the carbonate of bismuth in 400 ccm. of water, taking seven or eight exposures during the forty-eight hours subsequent at fifteen seconds. He finds most of the "food" has passed the small intestine in between two and three hours. After four hours it is seen in cecum, ascending and transverse colon, and after six hours in the descending colon and sigmoid; these times within considerable limits. But there are two peculiarities of its onward course in the large intestine, (1) a retention in the cecum and (2) an impeded movement just before the splenic flexure is reached, the former most marked; in fact, food persists in the cecum for twenty-four hours, at which time the rectum holds almost all the rest of the excrement. X-ray plates and autopsy findings agree on this retention of food in the cecum, a possible explanation being that relative to the rest of the colon the cecum is a thin-walled repository, perhaps of atavistic function, with slight motive force and possessing antiperistaltic motility, for which latter the author cites clinical evidence. In case of chronic constipation and enteroptosis, sluggishness at the two points mentioned is especially noticeable and must be of importance in explaining certain abdominal symptoms. The author has seen gas collected in front of the splenic flexure, the patient complaining of pain; then after the pain had passed off no gas was to be seen. He also points out the probable significance of this retention in connection with chronic appendicitis and the increasing number of disorders generally attributed to absorption of substances from the intestinaal tract.

Cannon's earlier and similar experiments on cats are carefully reviewed, and his observations largely corroborated and his theories generally accepted. Six plates appended.

3. Caro investigated experimentally the question of heart hypertrophy following prolonged administration of digitalis, and concludes that this drug causes from its selective action on the myocardium a true hypertrophy. He treated 7 rabbits and 4 dogs with moderate doses of digalen and digitalis subcutaneously over a period of two to three and one-half months, with occasional omissions by which cumulative effects were entirely avoided. The conditions of experiments were as good as possible, young animals being employed, and controls being of the same litter as animals experimented upon. His tables show, first, that heart hypertrophy regularly follows the prolonged use of digitalis preparations, and, second, that no other organ is similarly influenced. Changes in blood vessels were not constant and so could not be the primary cause of the cardiac hypertrophy.

He feels that possibly digitalis should be given in anticipation of great cardiac strain, as prophylactic.

A summary of other work on the same subject and a bibliography comprise more than one half of the paper.

5. The authors examined seven healthy persons and four cases of heart disease with the Uskoff tonometer to determine effects of work upon maximum, minimum and amplitude of blood pressure. No constant variations were obtained. The authors tested the instrument with others and found it essentially accurate. [J. B. A.]

Obituary.

FRANCIS COLLAMORE, M.D.

IN the death of Dr. Francis Collamore, which occurred Aug. 18 at Pembroke, Massachusetts loses a widely respected citizen and physician of the old school. Dr. Collamore was born Dec. 7, 1825, was graduated from Dartmouth Medical School in 1846, and after beginning practise in Braintree removed to Pembroke where the Collamores, father and son, have practised uninterruptedly for more than one hundred years. At the time of his death Dr. Collamore was the oldest member in point of time of The Massachusetts Medical Society and the last of the group of physicians who organized the Plymouth and Hatherly Medical Societies. In addition to his professional activities he was a representative to the General Court in 1881, a member of the school committee of this town and town treasurer for a long period. For fifty years he was justice of the peace and wrote a number of papers on the history of his native town. Dr. Collamore was the oldest subscriber of the BOSTON MEDICAL AND SURGICAL JOURNAL, which he took regularly for fifty-three years.

Correspondence.

SOUTHAMPTON AND THE ISLE OF WIGHT.

[*From Our Foreign Correspondent.*]

SOUTHAMPTON, Sept. 2, 1910.

Mr. Editor: Southampton is a city of many interesting associations, and preserves to this day numerous memorials and suggestions of its past. Along the shore of its beautiful bay still runs Canute Road, by the waters where King Canute is reputed to have given his famous rebuke to the flattering courtiers in the days of the Danish dominion over Britain; and the solid old Norman walls and gates and towers, still encircling half of the ancient town, recall the times of a later conquest. On the buttresses of the bar gate used to be the paintings, now removed to a museum for safety, representing the victory, in single combat with the giant Ascupart, of Sir Bevis, the half-legendary hero of Southampton, whose name, doubtless originally Beauvois, still persists in the form Beavis or Bevois as a local surname to be seen on shop-signs and door-plates. Near another of the gates, in Blue Anchor Lane, is preserved the palace of King John, which that monarch is said to have inhabited for a time after the departure of Richard, his lion-hearted brother, from the port of Southampton at the head of his Crusaders to the Holy Land. Southampton saw another royal embarkation, made much more familiar to us by Shakespeare, when in 1415 Henry V set sail here for the invasion of France. Henry stayed in Southampton for some days before his departure, and it was here that the conspiracy against his life, so graphically narrated in the play, was opportunely brought to light. In the dingy little *Domus Dei*, near the royal quay, is a tablet recording the burial there, after execution, of the three conspirators, —"Richard, Earl of Cambridge; Lord Scrope, of Masham; and Sir Thomas Gray, of Northumberland." This building, formerly a hospital or almshouse, has now been used for several centuries as a place of worship by the descendants of Huguenot refugees in Southampton, much as the crypt of Canterbury Cathedral is used by the French silk-weavers of that town.

One other historic embarkation from Southampton has especial interest for us. In the summer of 1620, just two hundred and ninety years ago, the *Speedwell* and the *Mayflower* sailed from this port to found a new nation beyond the seas. The unseaworthiness of the *Speedwell*, which had already brought the Pilgrim Fathers from Delfthaven in Holland, compelled them to stop at Plymouth, whence the *Mayflower* finally sailed alone on Sept. 6 of the same year. Southampton, however, was their original port of departure, and it seems appropriate that the beginnings of our own New England should be so linked with this ancient and historic maritime town. One is tempted to indulge in much speculation and revery, standing at sundown on a height overlooking Southampton Water, and in imagination to contrast those frail craft of momentous destiny with the huge American liners that now come wearing up the Solent, back from the great Republic of the West.

The interest and associations of Southampton, however, are not all within its walls. On the southeast shore of the harbor, secluded in a quiet wood, is Netley Abbey, whose ruin, like those of Tintern and Fountains, is far more beautiful than its original perfection could ever have been. Such a ruin is infinitely stimulative to the imagination, for it not only gives boundless opportunity to reconstruct the past but illustrates that shattered aspiration may be even greater than splendid achievement. Far more prosaic than the abbey, and doubtless far more useful than it was, is the Netley Military Hospital, which stretches its fine brick front conspicuously along the waterside. It has accommodation for over a thousand patients and is said to afford unusual opportunity for the study of tropical and cutaneous diseases. We did not visit it, however; as vacation shortens, abbeys grow more attractive than hospitals.

Over against Southampton Harbor, which it protects, as a gigantic breakwater, from the rage of the "merry channel chops," lies the Isle of Wight, sometimes called the island of centenarians, on account of the reputed salubriety of its climate. One would rather expect the climate to be particularly bad, yet it does not seem to be so, and the island is much resorted to by invalids, especially by patients with phthisis and other diseases of the lungs. Along the south coast of Wight, just west of Ventnor, is the Royal Victorian Hospital for Tuberculosis, consisting of a series of larger and smaller buildings extending for over a quarter of a mile along the shore. There were other things in the island, however, that interested us more and we spent a day very pleasantly coaching and traveling through its picturesque territory. Just beyond the Victorian Hospital is a ravine which rejoices in the magnificently swashbuckling name of Blackgang Chine. Visions of pirates and smugglers rose at once in our minds, but we were assured that the abyss harbored nothing more formidable than lizards. At the western extremity of the island are the so-called "Needles," two detached rather stumpy masses of chalk rock projecting above the waters of Alum Bay. They are very beautiful in the dazzling sunshine, but do not really look like needles at all, unless like the point of a cambric needle seen through a microscope. Carisbrooke Castle, near Newport, was interesting for its association with Charles I, who was imprisoned here before his execution. One is also shown here the old well, conveniently placed so as to receive all the drainage from the castle, but whose waters, once doubtless deemed delicious, are now considerately labelled "not fit to drink." Let our improvement in some of the details of life console us for the loss of its more romantic elements.

Our last day at Southampton was spent in an excursion to Chichester, a quaint old town in "sweet Sussex by the sea." It is of Roman origin, built along two main streets intersecting at right angles. In the square at this point of anastomosis is the "mercat-cross," like a crown built of stone, indicating the site of the old market-place, and large enough to afford shelter to a number of marketers in inclement weather. The cathedral is hard by, surrounded by a modest close, in which stands its unique detached bell-tower. Within the church are many monuments, one of them to the poet Collins, who was born and who died in Chichester. One of the most interesting tablets was that recording the life and virtues of "John Arundel, M.D., Fellow of Exeter Coll., Oxon., and in 1420 Proctor of the University. He afterwards took his doctor's degree in Physick." He also took orders and held many ecclesiastical offices, finally becoming Bishop of Chichester. "He was Chaplain and first Physician to King Henry VI, being allways in great favour with that Prince." In 1459 he was promoted to the see of Chichester, and, concludes the inscription, "he satt heere about 19 yeares, and dying ye 18th of October, 1477, was Buried under this Great Tomb." After more than four hundred years, let us hope that our brother physician, who healed souls as well as bodies, sleeps well in his great tomb, and that after our brief labors we may find as pleasant a resting-place as his, surrounded still by the successors of those to whom he ministered.

Not far from the cathedral is the Hospital of Saint Mary, another one of the many almshouses surviving out of the Middle Ages. This particular institution, still persisting on its ancient foundation, accommodates under its roof eight old women, each in a separate cubicle with sitting room. Each of these poor beneficiaries receives, besides her board and lodging, a dole of tenpence a week, and in addition "ten shillings every other year in lieu of a new gown." It would seem that most of the fallacious vanities of life must be abrogated under such a regimen. After all, the essentials of existence, like those of happiness, can be comprised within a very small compass.

Perhaps it is hardly fair to put down all our pleasures of the past few days to the credit of Southampton. Nevertheless, the charm of the town seems to extend over all the country round about; and we shall not soon forget our stay here since the welcome night when we put in as returning pilgrims, and heard our own tongue spoken once more, and set foot again on the homelike shores of merry England.

MEDICUS PEREGRINUS.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED SEPT. 7, 1910.

PETTUS, W. J., assistant surgeon-general. While on leave in England, directed to proceed to Southampton, Liverpool and Glasgow upon special temporary duty relative to measures for the prevention of the introduction of Asiatic cholera into the United States, and then resume leave status. Sept. 2, 1910.

KERR, J. W., assistant surgeon-general. Detailed to represent the Service at the annual meeting of the American Public Health Association, to be held in Milwaukee, Wis., Sept. 5-9, 1910. Aug. 30, 1910.

CARTER, H. R., surgeon. Detailed to proceed to certain ports in Europe upon special temporary duty relative to measures for the prevention of the introduction of Asiatic cholera into the United States. Sept. 2, 1910.

WASDIN, EUGENE, surgeon. Granted one month's leave of absence from Aug. 22, 1910, on account of sickness.

COBB, J. O., surgeon. Directed to proceed to Manitowoc, Wis., upon special temporary duty. Sept. 1, 1910. Detailed to represent the Service at the annual meeting of the American Public Health Association, to be held in Milwaukee, Wis., Sept. 5-9, 1910. Sept. 2, 1910.

GEDDINGS, H. D., surgeon. Directed to proceed to Marseilles, France, and Genoa, Italy, upon special temporary duty relative to measures for the prevention of the introduction of Asiatic cholera into the United States, and then rejoin station at Naples, Italy. Sept. 1, 1910.

MCMULLEN, JOHN, passed assistant surgeon. Granted twenty-one days' leave of absence from Sept. 3, 1910.

ANDERSON, JOHN F., passed assistant surgeon. Granted one day's leave of absence, Sept. 2, 1910, under paragraph 189, Service Regulations.

WILLE, C. W., passed assistant surgeon. Directed to proceed to Ashtabula, O., upon special temporary duty. Sept 1, 1910.

LLOYD, BOLIVAR J., passed assistant surgeon. Granted twenty-nine days' leave of absence from Aug. 20, 1910.

SPRATT, R. D., passed assistant surgeon. Granted one day's leave of absence, Aug. 27, 1910, on account of sickness.

FROST, W. H., passed assistant surgeon. Directed to proceed to Grundy Center, Ia., upon special temporary duty. Aug. 29, 1910.

MULLAN, E. H., passed assistant surgeon. Granted five days' leave of absence from Aug. 1, 1910, under paragraph 191, Service Regulations.

ASHFORD, F. A., passed assistant surgeon. Granted one month's leave of absence from Aug. 30, 1910.

KOLB, LAWRENCE, assistant surgeon. Granted seven days' leave of absence from Aug. 28, 1910, under paragraph 191, Service Regulations.

DREW, A. D., acting assistant surgeon. Granted thirty days' leave of absence from Sept. 15, 1910.

MARR, H., acting assistant surgeon. Granted fifteen days' leave of absence from Sept. 5, 1910.

MOORER, M. P., acting assistant surgeon. Granted six days' leave of absence from Aug. 14, 1910.

O'NEILL, ARTHUR A., acting assistant surgeon. Granted ten days' extension of leave of absence from Aug. 9, 1910, on account of sickness.

RANSOM, S. W., acting assistant surgeon. Granted thirty days' leave of absence from Sept. 1, 1910.

SCHUSTER, B. L., acting assistant surgeon. Granted three days' leave of absence from Sept. 7, 1910.

WALKER, T. D., acting assistant surgeon. Granted one day's leave of absence, Sept. 8, 1910.

WETMORE, W. O., acting assistant surgeon. Granted three days' leave of absence from Aug. 11, 1910, under paragraph 210, Service Regulations.

STEARNS, WILLIAM L., pharmacist. Granted twenty-one days' leave of absence from Sept. 6, 1910.

STIER, CARL, pharmacist. Granted one day's leave of absence, Aug. 27, 1910, under paragraph 210, Service Regulations.

OTT, C. R., pharmacist. Granted one day's leave of absence, Aug. 25, 1910, under paragraph 210, Service Regulations.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING SEPT. 17, 1910.

LONGAUGH, R. I., passed assistant surgeon. Commissioned passed assistant surgeon from May 4, 1910. Sept. 9.

DONELSON, M., passed assistant surgeon. Detached from the Naval Hospital, Naval Home, Philadelphia, Pa., and ordered to duty at the Naval Hospital, Newport, R. I. Sept. 13.

REED, E. U., passed assistant surgeon. Detached from the "Philadelphia" and ordered to the "Princeton." Sept. 13.

MILLER, J. T., passed assistant surgeon. Commissioned passed assistant surgeon from June 27, 1910. Sept. 13.

CASTO, D. H., assistant surgeon. Detached from the "Princeton" and ordered to the "Philadelphia." Sept. 13.

HERMESCH, H. R., passed assistant surgeon. Commissioned passed assistant surgeon from July 12, 1910. Sept. 14.

MCDOWELL, R. W., assistant surgeon. Discharged from treatment at the Naval Hospital, Norfolk, Va., and ordered to the Naval Medical School Hospital, Washington, D. C., for treatment. Sept. 14.

RECENT DEATHS.

DR. J. FRANK GILLESPIE, of the Borough of the Bronx, New York City, died on Sept. 14, in the forty-second year of his age. He was born at Parrsborough, Nova Scotia, and was graduated from the Baltimore Medical College in 1897. At the time of his death he was physician for diseases of the eye ear, nose and throat to the out-patient department of the Lebanon Hospital.

DR. CHARLES COOKE RANSOM, of New York, died on Sept. 13, at the Faxton Hospital, Utica, shortly after an operation for the relief of intestinal obstruction. He was a native of Richfield Springs, N. Y., and fifty years of age. He was graduated from the University of Buffalo Medical College in 1883 and was a visiting physician to the City Hospital on Blackwell's Island. For many years he had practised during the summer at Richfield Springs, and had devoted special attention to the study of gout and rheumatism.

THE PLASTIC SURGERY OF THE OVARIES AND TUBES.

BY WALTER C. SEELYE, M.D., WORCESTER, MASS.

In dealing with the surgical treatment of ovaries, it is necessary to bear in mind the effect of these organs, both in their normal and pathological conditions, upon the organs correlated with them. In the past few years much work of interest and importance has been done by physiologists on the subject of hormones (ὁρμάω, to arouse, excite) or the active principle of the internal secretion of glands. In experimental work on animals, Bayliss and Starling obtained an explicit example of how one organ controls the activity of another organ by means of a specific chemical substance given off to the blood. Edkins states that this effect is not a nervous reflex, but a stimulation of one organ by chemical products formed in another. Howell says: "We might modify the definition so far as to designate as hormones those substances in solution which, conveyed from one organ to another through any of the liquid media of the body, effect a correlation between the activities of the organ of origin and the organ on which they exert their specific effect." Among the hormones of the various glands of the body that are either proved or assumed to exist, and which are held responsible for certain well-known correlation of functions, are mentioned a hormone in the ovary which controls the growth of the uterus and the processes of menstruation, and a hormone which controls the implantation of the fertilized ovum and growth of placental tissue.

In "The Making of Species," by Dewar and Finn, it is shown that the development of secondary sexual characteristics is dependent on the secretion of these hormones. These secondary sexual characteristics usually affect the skin, especially epidermic appendages and the superficial parts of the skeleton, or whole limbs and appendages. Experiments of injecting the extract of the testes of a cock into the hen bird have produced wattles and tail feathers in the latter similar to those of the cock. Many birds in captivity lose some of the beauty of their plumage, and another curious fact is that the male plumage sometimes appears pathologically in the hen birds, more especially in those that have become sterile from age or disease. Such phenomena as these suggest that in some cases the bright colors of the male may be pathological and that the hormones secreted by the male sexual cells may exercise an injurious effect on the body tissue. Further investigation may prove, what at present may be reasonably assumed, that more of the functional disorders of the uterus have their origin in pathological conditions of the ovaries.

In dysmenorrhea, the prevailing opinion at present is that mechanical obstruction, such as by membranes or by flexions of the uterus, are not possible causes of this condition. It has been many times proven that obstruction is not absolutely present in these cases, that probes of small caliber can invariably be passed into the uterine cavity, and that the flow of blood is so slow that any patency whatever of the uterine canal would allow the blood to pass, even if violent spasmodic contractions should momentarily shut off the canal. There is every reason to believe, therefore, that the pain is due to the abnormal spasm rather than to any obstruction to the flow. It has, on the contrary, also been well shown that where there was from some cause complete obstruction, pain has been absent. Spasmodic contractions of the uterus are generally acknowledged to be the cause of pain in dysmenorrhea, and only about one third of women menstruate without pain. But it is the cause of this abnormal spasmodic contraction that has given rise to so much perplexity in the question. Some writers have attributed it to a cervicismus, or hyperesthesia of the mucous lining of the cervical and uterine canal with a tight contracted cervix. The least touch of a probe on this sensitive tissue may cause great pain, and the natural conclusion is that the flow of blood and membranes over this surface causes pain, and thence the spasm of the uterus. But the fundamental cause must lie deeper, and if the perfectly normal functions and painless contractions of the uterus during menstruation, in the fortunate one third of menstruating women, are regulated by the properly balanced hormones from the ovaries, it seems reasonable to suppose that any slight abnormality in the ovaries may upset that balance and so produce the condition of contracted cervix and spasm of the uterus in dysmenorrhea.

The experimental work on this subject is still open for further investigation. It is evident, however, in the limited field of observation, that dysmenorrhea and often other irregularities of menstruation are invariably associated with pathological ovaries, with or without abnormalities in the tubes. Gibbons, of London, says: "When the amount of properties of the ovarian secretion are absolutely normal, no alteration takes place in the regular menstruation, but where it contains some abnormal constituent, or its elements are not duly proportioned, then the action of the blood causes the secretion preceding menstruation to irritate the uterine mucous membrance and give rise to the reflex action leading to painful contractions." With perfectly normal acting ovaries, then, may be associated a normal menstrual life, which is in turn associated with normal sexual instincts and fertility. For these reasons it is desirable to do all that is possible toward preserving or restoring these important functions by reparative operations on the ovaries and tubes.

Surgical treatment of ovaries and tubes has passed through several periods of development, from extreme radicalism to extreme conservatism, till now, in the light of the history of experience, it is possible to formulate a little more closely the present attitude lying somewhere between these two extremes. No general rule can be applied for all cases, but each must be a study by itself and judged according to age, domestic conditions of life, number of children, miscarriages, menstrual

* Read before The Massachusetts Medical Society, June 7, 1910.

history past and present, inflammation past or present, acute or chronic, and neurasthenic conditions.

With these points in view I will attempt a classification of cases as a guide to the mode of procedure in any given case.

1. Young, unmarried women, or women in early married life, with no pregnancies, who have had continual and severe dysmenorrhea, constitute the first class in which the very history demands a pelvic operation.

The findings are almost invariably unicystic or polycystic ovaries, often bound down by adhesions into the posterior cul-de-sac, or to the sides of the pelvis, varying in size from ovaries slightly larger than normal to those four or five times that size. Considering that such a woman has the best part of her life before her, she represents the class for maximum conservatism.

If both ovaries are only slightly enlarged and finely polycystic throughout, they are better left and not resected, but must be carefully freed from any abnormal positions and adhesions that they have usually acquired. They must be then brought high up in the pelvis, taking care at the same time that the tubes are free. The ovaries in this case may be gently suspended or hitched over to a higher position on the broad ligament, or even, in some cases, passed through the broad ligament and fastened to the anterior surface.

If one ovary of this class is as above described, and the other greatly increased with one or a few cysts, the latter may be resected if the main body of the ovary is normal; but if there is a mere shell of normal tissue left, total extirpation is the safer method, leaving the other ovary whole. If both ovaries have undergone serious cystic degeneration and there is any normal tissue left, it seems reasonable in this particular class to preserve part of one ovary at least. It seems more reasonable to preserve the function of menstruation, and the effect of properly balanced hormones, if possible, in a woman of this class, in spite of the chance of a subsequent operation, than to sacrifice all at the first blow.

In resection of ovaries in such cases, there must be great care to preserve the normal circulation and avoid constriction, which leaves the ovary prone to further cystic degeneration. A maintenance high in the pelvis is generally recognized as an important step after any cutting operation on the ovary. By so doing the return circulation may be made, if possible, more free than before, and thus help in naturally reducing the ovary to a normal condition. In all my cases of resection of ovaries, plain catgut, No. 1 or 2, is used in an over-and-over suture, care being taken to have good approximation of the edges to avoid adhesions, and also to leave no dead spaces for a chance of hematoma.

2. Married women between thirty and forty years of age, with one or more children, form the second class.

Here the point of view changes somewhat. There is less of the woman's menstrual life to be conserved at this point, and certain sacrifices of ovaries may be made that would be unwise in the first class.

Where both ovaries are badly involved in cystic degeneration, and evidently undermining the health, the point of conserving the woman's condition may outweigh that of conserving the ovary, with all its possibilities of future return of trouble. In such a case the patient's attitude of mind must be carefully considered, and unless she insists on ovarian tissue being left, and bearing the responsibility herself, such ovaries should be removed *in toto*.

J. O. Polak believes the field of ovarian resection a very limited one. In 300 cases thus operated he found that 41, or 12%, returned for further operation, requiring ablation of the remaining ovary or of the remaining portion of a resected ovary that had been left at the primary operation.

In cases of cystic degeneration of this class, careful judgment is necessary as to the proper procedure. This, it seems to me, depends upon how completely the ovary is involved. If the cyst formations are large and confined pretty well to one end of the ovary, it is reasonable to believe that resection may be done with good results, but if there is no considerable part of the ovary free from degeneration it is doubtless best to remove the entire ovary. On the other hand, the ovaries that are only slightly larger than normal, and involved in the tiniest cystic formations, are best let alone and secured in a high position.

Cysts of the corpus luteum sometimes grow to considerable size and can be shelled out of their capsule, leaving normal ovarian tissue behind. In all forms of large tumor growths of the ovaries, whether benign or malignant, there is no justification in leaving any portion of the ovary. But a difference of opinion arises in the condition where one ovary is perfectly normal and the other malignant, whether to remove the normal ovary also. No less an authority than H. A. Kelly says: "If malignant disease exists on one side, it is safer to remove the opposite side also." Other writers do not favor such a procedure, and the individual case must be judged according to circumstances.

3. Women on a near approach to the menopause form a third class in which the minimum of conservatism is reasonable.

Abnormal ovaries with any probability of causing future disturbance should unhesitatingly be removed. Any attempt at resection or transplantation of ovaries, combined with plastic operations on the tubes, either to preserve the effect of hormones, menstrual life or possibility of pregnancy, seem unreasonable in this class of cases. A rare exception, however, may occur in a woman who is anxious to risk everything for the remote chance of a first pregnancy.

4. The fourth class comprises cases of acute or chronic inflammation, and those that have completely subsided from the same.

In cases of acute inflammation of tubes and ovaries it is the generally recognized attitude, both abroad and in America, to wait, if possible, till the acute symptoms have subsided. If this is not possible, a fact to be determined by the run of the

patient's condition, open drainage must be obtained either by vaginal puncture or median incision into the pelvis from above, and any more extensive operation deferred till a later date. Any plastic operations in the acute stage can be nothing but dangerous and are not to be considered.

In chronic inflammation there must be a careful consideration of the woman's condition, taking into account the duration of the inflammation. In those cases of long standing, where the woman's health is at stake, total extirpation of tubes and ovaries may be necessary, but many of them offer favorable conditions for plastic work. If the ovaries are normal and the inflammatory area or pus sac is definitely confined to a small portion of the tube, this may be excised without contaminating the surrounding area, and the proximal end of the tube left patent by sewing the mucous membrane to the peritoneal surface.

J. Clarence Webster resected the fimbriated end of a tube, and at a later date found, on opening the abdomen, that fimbriæ had formed at the resected end of the tube.

Plastic work on the tubes has been unsatisfactory to a large degree, and Polak has abandoned the practice altogether, as he found the results disappointing; but if such work is to be done at all, the most favorable class for its practice is that which has gained complete recovery from the inflammation of the tubes. Here the tubes will almost invariably be occluded by adhesions and cicatrization. Pregnancy is the only consideration for plastic operations on such tubes, for menstruation will usually continue normally provided the ovaries are left. Even though such operations are discredited by some, if, from the woman's standpoint, a possibility of pregnancy is the greatest thing at stake, it seems reasonable to take advantage of every measure that may restore such a function. Plastic operations on the tubes of these cases can do no harm and may bring untold happiness to a family by making possible the birth of a child, as has been the case in a few instances, even where the tubes were partially destroyed and a resected ovary was transplanted to the uterine portion of the tube.

F. H. Martin has obtained pregnancy by this procedure, which he calls homotransplantation. Kelly reports a case where but one tube was left and one ovary on the opposite side, in which pregnancy followed.

5. The fifth class of cases is represented by young women in early life who have had total extirpation of both ovaries and are contemplating marriage.

These are open to a last resort, namely, transplantation. The earlier it is performed, the more likelihood there is of any success. Martin, in his interesting experiments of heterotransplantation, or the transplantation of a portion of an ovary from one woman to another, cites a few cases in which menstrual life was partially restored, and states the report of another case in which conception followed.

6. The last class, that of neurasthenic cases, must always be judged most guardedly.

Whether their symptoms are from causes of a pathological or functional nature must be absolutely determined, if possible. The old saying, "Never operate on a neurasthenic," is perhaps only too true when bearing upon the sexual organs. It is safe to say that these patients belong in the first place in the hands of a neurologist, and only as a last consideration should any attempt be made in reparative operations in such cases.

The 35 cases on which I have operated in the past two years, 9 single and 12 married, or 21 in all, represent classes 1 and 2, with dysmenorrhea and irregularities in catamenia; 10 had resection of one ovary; 5 had double resection of ovaries; 6 had resection of one and extirpation of the other ovary.

Of these, all but one had marked immediate relief from dysmonorrhea, and the relief has held to the present time.

In two of these cases dysmenorrhea was of much severity, so that the patients had to go to bed for several days at each period. The intervals were shortened, and the patients had only about one week free from pain between periods. These were not only relieved of dysmenorrhea, but the periods became normal in time.

The one case unrelieved was of the first ten and was one in which resection or extirpation of the untouched ovary ought to have been done, for it was large and cystic. She will probably return for secondary operation.

Of the remaining 14 cases, 4 were over forty years of age and had chronic inflammation of both tubes and ovaries. Total extirpation was performed in each. One was a large cyst of one ovary, which was removed; another was a cyst combined with a pus tube on one side, and was removed with the tube. Eight had resection of one or both tubes on account of occlusion from past inflammation. The lumen was left patent, and the ovary brought into close contact with the proximal end of the tube. In these 14 cases, the late results of 4 are unknown; the rest have been in good health with no symptoms. No pregnancies have yet been reported.

In conclusion, I would emphasize, first, the plea for more abdominal operations on the pelvic organs in cases of severe dysmenorrhea, and, second, the importance of a classification as an aid in determining the mode of procedure in a given case for operation on the ovaries and tubes.

DISCUSSION.

DR. ERNEST B. YOUNG, of Boston: We have listened to a very interesting paper upon an important subject. A great deal of our pelvic surgery in the hospitals, on account of the condition of the patients and their social station, has to be of a radical nature, and it is a good thing to occasionally consider the more conservative methods of treatment.

All the principal points have been well touched upon by the speaker. There is one point concerning which I would like to say a word, and that is in relation to operations upon the tubes after inflammatory conditions in the pelvis. If we are to obtain favorable results we must proceed cautiously, and allow time for as complete a resolution as possible before beginning. Some German investigated these cases of tubal infection, made cultures, and found it was nine months on the average before the various cocci in the tubes became harmless. So a considerable time must be allowed to elapse after infection before we can hope to operate with good results or with safety to the patient.

Then, in the next place, various investigations have shown that operations of a conservative nature upon the tubes are much less successful than upon the ovaries. Dr. W. L. Burrage published two interesting papers upon this subject some years ago. He divided the cases into gonorrheal infections and those which arise from pelvic infection after miscarriage; or rather, I should say, from the infections with the more common pus cocci after miscarriage and full-term labor.

The conditions in these two classes are entirely different. In gonorrhea we find large tubes with heavy walls, thickened and intimately and broadly adherent to the bottom of the pelvis and to surrounding structures — often filled with pus. Thus we are working, as a rule, with hopelessly diseased tissues which are unable, I believe, to perform their functions under any conditions. If we destroy adhesions, large raw surfaces are left to contract new adhesions, and the conditions at the end are apt to be no better than when we began. However, we need not entirely despair, for I know of a case where one ovary and tube were removed and the other ovary left with a resected tube. This woman became pregnant four times after the operation and gave birth to four living children. But this is the exception, not the rule. I have personally never seen a successful plastic upon the tubes after gonorrheal infection, and where cases have apparently recovered perfectly, and the abdomen has been opened subsequently, the abdominal extremities of the tubes have been always closed.

In the septic infections after miscarriage and labor, due to the more common cocci, the conditions found are entirely different. The brunt of the inflammation in this class falls upon the cellular tissues of the pelvis, and the tubes are frequently little affected. When the abdomen is opened at the height of the process the tubes are often perfectly free and their ostia patulous. Then, again, they less often contract the deep, broad pelvic adhesions which we find in the gonorrheal cases; for the infiltrated broad ligaments lift the tubes out of the pelvis and the adhesions are of an entirely different character. In the gonorrheal cases, as I have said before, the adhesions are very dense, and when broken they bleed. In the other class they are long, diaphanous, and have a very poor blood supply. They do not bleed when broken, and no large raw surfaces are left for future peritoneal adhesions. After the worst cases of puerperal sepsis, even with the streptococcus, the tubes are frequently open, the walls are thin and the feel is that of normal tissues. In the post-puerperal cases it may be possible to do something to aid pregnancy by breaking up such adhesions as constrict or displace the fimbriated extremity of the tube; but I do not believe, except where the tubes are absolutely closed, that we can do much to help pregnancy by operation, for if the tubes are patulous they are in condition to fulfill their purpose as well before as after any plastic.

Thus it appears to me that the prognosis in all cases of conservative operation upon the tubes must depend primarily upon the physiological condition of the tube itself and upon the extent and nature of the adhesions. After gonorrheal infection the chance of success is very slight. On the other hand, after puerperal infection with the ordinary pus organisms, the opportunity for success is vastly greater.

DR. MALCOLM STORER, of Boston: I have been much interested in the various ingenious theories advanced by Dr. Seelye to account for ovarian dysmenorrhea. In the cases of pain preceding menstruation, however, I cannot but feel that a quite sufficient explanation is to be found in the fact that it may be painful for an ovary to enlarge with the congestion coincident with menstruation if it is buried in a mass of adhesions.

I have for years been strongly in favor of the utmost conservatism that is consistent with good work, in cases when a child is desired, and should even go so far as to say that while, of course, the woman's life is the first consideration, we should have the greatest possible hesitation before performing an operation that will render further childbearing impossible. The reproach is sometimes brought against these conservative operations that often a secondary operation is needed. That, doubtless, is so; but if, between the two operations, a previously sterile woman gives birth to a child, I think in most cases she would regard the second operation as a very slight price to pay.

I agree thoroughly with what Dr. Seelye has said about avoiding operation, other than vaginal drainage, in the presence of acute inflammation. One can, however, generally operate with impunity long before the nine months some writers have mentioned as necessary to elapse after the acute stage. I regard two or three weeks quite long enough to wait in most cases.

I do not at all agree with the writers Dr. Seelye has quoted who are so skeptical as to the benefit of plastic operations upon the tubes. One is apt to be influenced by one's personal experience, and the happiness of several mothers upon whom I have performed plastic tubal work has not served to mitigate my enthusiasm at all. In one case I removed an ovarian tumor on each side, each containing some two quarts, and left on one side a tiny fragment of an ovary. At the same time I built a new ostium in a hydrosalpinx on one side and resected the middle third of the other tube, anastomosing the healthy fimbriated end with the uterine stump of the tube, and the woman got pregnant within a year and has had another child subsequently.

Dr. Seelye has spoken of ovarian transplantation. I can contribute a case.

Some years ago a woman who had had one ovary and both tubes removed told me that she wished to marry again, but her proposed husband insisted that first something be done that should render pregnancy at least a possibility. I accordingly split the fundus uteri and sewed one half of her ovary into the uterine wall so that its surface projected into the uterine cavity. Two years later the woman had all the symptoms of pregnancy, but at three months gave birth to a fleshy mole, evidently a very early pregnancy gone wrong. I feel that this subject of ovarian transplantation is one of great promise.

I have enjoyed Dr. Seelye's highly suggestive paper very much.

Dr. E. W. Cushing, of Boston: I do not know whether I understood the reader correctly as saying that the common dysmenorrhea of young women was to be attributed largely to disease of the ovaries. If I did so understand correctly, I beg leave to differ with that view, for it is evident that the simple dilatation of, and putting a stem in, the uterus will in the great majority of cases cure that dysmenorrhea without opening the pelvis. Where there are adhesions following inflammation, it is a very different class of cases. In regard to the removal of cystic ovaries, not ovaries with a cystoma, but with many little cysts in them, I should be very loath certainly to remove both. We have found good — in fact, excellent — results by resecting, but the old method of simply opening the cysts — letting the fluid out by puncture with a needle — is often all that is required. These little cysts are caused presumably by a thickenng of the outer wall of the ovary, which does not allow the exit of the ovum and the fluid which accompanies it.

It is a sad and serious thing to remove both ovaries in a young woman. "*Crede experto.*" Menstruation is to her the sign of her womanhood. She soon forgets the pains which seemed to justify the operation, and she grieves over the loss of potential motherhood, and yearns for the baby which she cannot ever have, and often refuses the offer of marriage she would otherwise gladly accept.

I have been through the different stages of which the writer speaks — of the removal of ovaries that should be saved, of the saving of ovaries that should be removed, until I have got to the middle course. But I am persuaded that at present there is a vast number of ovaries removed unnecessarily, a vast number of operations done which do not need to be done, where there is dysmenorrhea. With a heavy subinvoluted uterus and all the suffering that goes with it, the tendency now is to lay the blame immediately to the ovary, and, instead of curing the subinvolution and endometritis, and supporting the ovaries, many enthusiasts remove the ovaries and are as proud as Jack Horner of their deed.

In regard to surgery of the tubes, I believe in it. I believe in opening the tubes where there are adhesions around the end of the tube, sometimes removing the end of the tube and splitting it open in order to form a new ampulla and provide for conception. In repairing tubes in that way I have had a number of cases where conception has occurred, although in one or two cases I have been given to understand that the patients wished I had not opened the tube, as conception was unwelcome.

POST-OPERATIVE PNEUMONIA WITHOUT MORTALITY IN TWO THOUSAND CONSECUTIVE SURGICAL OPERATIONS AT THE FREE HOSPITAL FOR WOMEN.

BY W. P. GRAVES, M.D., BOSTON.

Recent reports by Risley and Munro on the frequency of post-operative pulmonary complications at the Massachusetts General and Carney hospitals respectively has suggested a compilation of the following statistics from the Free Hospital for Women, partly for the sake of comparison, and partly to make some further inquiry into the possible factors that may enter into the causation of these complications. The present series of cases dates from a time when accurate anesthesia records were instituted, and the number 2,000 was chosen for the sake of convenient comparison with the two reports mentioned above. Of these cases, 550 were uncombined laparotomies, 539 were laparotomies combined with vaginal and plastic operations, 65 were breast operations and the remainder were mostly plastic. This gives, therefore, a total of 1,089 laparotomies to serve as a basis of comparison with the statistics of Risley and Munro, each of whom analyzes 1,000 laparotomies; while it gives 911 cases not laparotomies as a basis of comparison with 920 cases not laparotomies reported by Risley.

The methods of administration of the anesthesia were as follows:

Gas and ether with the Bennett inhaler 259 times, anesthol with the open cone 6 times, ether by the drop method 124 times, ether with the open cone 1,591 times. The anesthetic, though for the most part given by medical students, who had short terms of service, was in every case under constant skillful supervision, so that in a partial sense its administration may be regarded as expert. Malinckrodt's ether was used in all cases. Of the 1,089 laparotomies, 20 developed pulmonary complications, of which 8 were bronchopneumonia, 3 were pleurisy and 9 were bronchitis. Of the 911 cases not laparotomies, 2 developed pulmonary complications, 1 being a pleurisy and 1 a bronchitis. The following is an analysis of the Free Hospital cases.

BRONCHITIS.

1. Resection of ovaries. Open cone. Bronchitis beginning third day after operation and lasting twenty-four hours.

2. Curettage, myomectomy, ventral suspension. Bennett inhaler. Bronchitis beginning second day after operation and lasting five days.

3. Amputation of cervix, vaginapexy, appendix. Open cone. Bronchitis beginning day following operation, lasting three days.

4. Appendectomy and internal shortening of round ligaments. Open cone. Bronchial cough starting immediately on recovery from ether and lasting through convalescence. (This patient had a small area in the right apex on entrance which indicated an old tuberculosis.)

5. Anterior and posterior colporrhaphy, ventral hernia. Open cone. Bronchial cough started four days after operation, lasting through convalescence, with slight evening temperature. (This patient had evidence of an old tubercular process of the right apex.)

6. Ventral and left inguinal hernias, appendectomy, Whitehead's operation. Open cone. Bronchitis starting three days after operation, cough lasting ten days. Stitch abscess in abdominal wound.

7. Internal shortening of round ligaments, appendectomy. Open cone. Bronchitis starting day following operation, lasting four days.

8. Fistula in ano. Open cone. Bronchitis beginning day following operation, lasting two days. Sepsis in wound.

9. Double salpingectomy, appendectomy, myomectomy, ventral fixation. Bronchial cough

beginning day following operation, lasting four days. Open cone.

10. Inguinal hernia, appendectomy, ventral suspension. Open cone. Bronchitis starting up on ninth day. (Previous tubercular history.)

BRONCHOPNEUMONIA.

1. Hysterectomy for pelvic inflammation. Bennett inhaler. Poor recovery from ether. Bronchopneumonia starting fourth day following operation lasting ten days. Sepsis of wound.

2. Hysterectomy and perineorrhaphy. Open cone. (Patient cyanotic and vomiting during operation.) Bronchopneumonia starting on third day and lasting two weeks.

3. High amputation of the cervix, ovariotomy, vaginapexy. Open cone. Bronchopneumonia beginning seven days following operation and lasting eighteen days. (Patient sixty-eight years old.)

4. Appendectomy, Gilliam's operation. Open cone. Bronchopneumonia started day following operation, lasting seventeen days. Sepsis of wound eleven days after operation.

5. Hysterectomy and appendectomy. Open cone. Bronchopneumonia beginning day following operation, lasting five days.

6. Inguinal hernia, myomectomy, salpingectomy. Open cone. Bronchopneumonia beginning day following operation, lasting thirteen days.

7. Anterior and posterior colporrhaphy, appendectomy, ventral fixation. Open cone. Cyanotic and vomiting during operation. Bronchopneumonia beginning three days after operation, lasting six days. Parotiditis on seventh day after operation.

8. Amputation of cervix, resection of ovaries, appendectomy, vaginapexy, perineorrhaphy. Open cone. Bronchopneumonia beginning two days after operation, developing into empyema. (Patient very sick.) Operation for empyema. Eventual recovery.

PLEURISY.

1. Double salpingo-oöphorectomy. Open cone. Pleurisy beginning day following operation, lasting two days.

2. Ovariotomy, myomectomy, appendectomy. Open cone. Pleurisy beginning day following operation and lasting four days.

3. Internal shortening of round ligaments, appendectomy. Open cone. Pleurisy beginning six days after operation, lasting three days.

4. Cervical operation for anteflexion. Open cone. Pleurisy beginning four days after operation, lasting three days.

A comparative table of figures from the three reports follows.

In the Massachusetts General and Free Hospital series each includes 3 previously tubercular cases which had post-operative flare-ups. In the Carney Hospital series, previously tubercular cases are excluded. It will thus be seen that the actual percentage of occurrence of post-operative lung complications does not differ very greatly in the three reports, although the Carney and Free hospitals appear to have some advantage over the Massachusetts General. This shade of difference is undoubtedly accounted for by the fact that in the Massachusetts General series a considerably larger number of cases were operated on in the presence of pus, or were desperately ill before operation. The higher percentage of mortality in the Massachusetts General may also be accounted for in the same way. A comparative study of the three series cannot but convince one that cases previously septic or desperately ill before operation are somewhat more susceptible to pulmonary complications, and, in case they do contract such complications, are decidedly more subject to a fatal termination. The absence of mortality in the Free Hospital cases confirms Risley's observation that post-operative pneumonia or bronchitis in clean cases is of shorter duration and of a less serious nature than in septic cases, the majority of the Free Hospital cases being clean cases.

	No. Cases.	Total Pulmonary Complications.	Pneumonia.	Bronchitis.	Deaths.
Massachusetts General:					
Laparotomies,	1,000	22	15	7	9
Not laparotomies,	920	5	Not stated		2
Carney:					
Laparotomies,	1,000	15	11	4	4
Free Hospital:					
Laparotomies,	1,089	20	8	12	0
Not laparotomies,	911	2	0	2	0

In order to compare the results of the three Boston hospitals mentioned in this report with the results in some of the foreign clinics, I have extracted some figures collected by Dr. John Homans and published in an article by him in the *Johns Hopkins Bulletin*, April, 1909.

Reference.	No. of Laparotomies.	Mortality Due to Lung Complications. Per Cent.
Korte (Bibergeil),	3,909	3.5
Czerny,	1,302	3.9
Von Angerer (Gebele),	1,196	6.43
Kümell (Grimm),	1,754	2.5
Von Mikulicz (Henle),	1,787	8.0
Von Mikulicz (Kausch),	1,881	2.4
Krönlein,	1,409	0.56
Trendelenberg (Läwen),	1,829	5.4
Lexer (Wolff),	976	12.5

It will thus be seen that the figures of the three Boston clinics have a decided advantage over those of the foreign clinics with the exception of Krönlein's. As Homans points out, Krönlein took extraordinary precautions of all kinds to avoid post-operative complications. The ether in all his cases was given by an expert anesthetist by the open method. Another set of figures also taken from Homans's article, the source of which is not stated, is shown in the table on the following page.

The last item in this table quotes 3,280 gynecological cases, and presumably represents in general the class of cases reported in the present article from the Free Hospital for Women. It, therefore, presents an opportunity to compare the Free Hospital cases with at least one other clinic of a similar nature.

Operations.	No. of Cases.	Died.	Died of Lung Complications.	Percentage of All Deaths Due to Lung Complications.
Stomach,	2,176	623 (28.63%)	181 (8.31%)	29.05
Bile passages,	1,042	132 (12.66%)	20 (1.92%)	15.15
Hernia,	1,601	60 (3.74%)	15 (0.93%)	25.00
Goiter,	3,526	34 (0.96%)	15 (0.42%)	44.00
Gynecological,	3,280	257 (7.83%)	50 (1.53%)	19.45

In order to make a more specific comparison between the Free Hospital cases and the cases designated as "gynecological" in the last item of the above table, I have analyzed 2,000 other cases from the Free Hospital for Women operated on consecutively before the beginning of the series which forms the subject of this paper. I find in this set of 2,000 cases that post-operative pulmonary complications occurred 15 times, of which 6 were pneumonia, 2 were pleurisy and 7 were bronchitis, figures which show a percentage of occurrence very similar to that of the other series of 2,000. In this second series, however, there were 2 deaths from pneumonia. One of the cases which had a pleurisy following the operation is reported in the records to have died some time after of tuberculosis of the lungs. Although I have not included this in the number of deaths, as the patient's physical examination was negative when she left the hospital, yet there is certainly some reason to suppose that the operation might have had some influence on the process. If we combine the two Free Hospital series, we will find that, out of 4,000 consecutive cases, 37 contracted post-operative pulmonary complications, from which 2 died, giving a 0.05% mortality from lung complications in the entire series. It is also of interest to note that the total mortality from all causes in the 4,000 cases, over half of which were laparotomies, is 0.97%. A comparison, then, with the gynecological cases quoted from Homan's article is as follows:

	No. of Cases.	Died.	Died of Lung Complications.	Percentage of All Deaths Due to Lung Complications.
Gynecological cases quoted by Homans,	3,280	257 (7.83%)	50 (1.53%)	19.45
Free Hospital cases,	4,000	39 (0.97)%	2 (0.05%)	5.4

It is of interest to study the present series of cases with reference to some of the more commonly assigned predisposing causes of pulmonary complications.

Operative shock has been suggested as a predisposing cause of post-operative pneumonia. A glance at the list of operations in the present series shows that few of them were of a very serious nature; in fact, only one of the cases (No. 1, bronchopneumonia) suffered shock from the operation. The operations of extreme gravity and those in which profound shock took place were singularly free from lung complications.

The method of administration of ether is claimed to have an important bearing on the occurrence of post-operative complications, many writers, among them Munro, claiming great advantages for the drop method. By far the greater majority of the cases in the Free Hospital series were anesthetized by the open-cone method, and the resultant figures of occurrence and absence of mortality go to show that the method of administration is not an important factor in causation.

The length of time of anesthesia administrations does not seem from this series of cases to be an important causative element. The majority of the 2,000 operations were long cases involving, usually, several operations under each anesthesia, 539 of them being combined abdominal and vaginal operations.

The average length of time per operation would undoubtedly exceed that of a large general surgical hospital; nevertheless, the occurrence of lung complications is not greater.

The age of the patient apparently is of little importance in calculating the chances of post-operative pneumonia, unless the age be considerably advanced, in which case the patient, of course, would be more susceptible to whatever may be the real causative element. Of the 22 cases, one patient was sixty-seven years old and one was sixty-eight. As the total number of operations on patients of this approximate age was not great, the occurrence of the two lung complications constitute a fairly high percentage and confirms the obvious apprehension that in operating on elderly people the danger of post-operative pneumonia must always be considered. On the other hand, there was no case of lung complication between the ages of forty-nine and sixty-seven, although a large number of patients of that period of life are included in the series. Fifteen of the cases suffering lung complications were under forty, while the average age was thirty-seven, which is approximately the average age of the entire series of the 2,000 cases.

The physical type of the patient is something which every surgeon naturally takes into consideration. The stout, short-necked patient, who is difficult to etherize, inspires a certain amount of apprehension as to post-operative pneumonia. An analysis of the 22 cases gives the following: Only 6 were large and fat, 8 were of medium physique, and 8 were small and thin, thus leaving the fat cases considerably in the minority.

Bad behavior under ether, such as cyanosis and vomiting, which depends sometimes on the physical characteristic of the patient, but more often on an unskillful administration of the anesthetic, does not seem to play an important part. Only 2 of the 22 cases are recorded as having taken ether badly.

Risley lays considerable stress on the preparation of the mouth as a preventive measure. Prac-

tically all of the 2,000 cases in this report had a thorough preparation of the mouth before operation. This fact may possibly account to some extent for the less severity of the lung complications in this series.

Wound sepsis in conjunction with post-operative lung complications is sufficiently common to attract serious attention. Of the 22 cases, 4 had sepsis in the wound, while one had parotiditis. This gives a 20% occurrence of wound sepsis. As the percentage of wound sepsis in the entire 2,000 cases is approximately 5%, some definite relationship between lung complications and wound sepsis is at least suggested. Septic embolism from infected wounds to parts of the body other than the lungs is occasionally seen where there is no doubt as to the process, the most striking example being the occasional occurrence of acute endocarditis following local sepsis. It seems, therefore, probable that some of the cases of post-operative pneumonia are caused by the lodging of septic emboli in the capillaries of the lungs, starting from a local sepsis of the wound. This theory, however, can account for only a small number, as in the majority of cases of lung complications there was no local sepsis, while in most of the cases of sepsis in this report the pulmonary complications antedated the appearance of the local wound infection; moreover, post-operative pneumonia is rare during the summer months, while wound sepsis is more apt to occur in hot weather than in cold.

Homans, in his article cited above, classifies pulmonary complications in three groups, namely: Ether pneumonias, hypostatic pneumonias and embolic pneumonias. All of the 22 cases of pulmonary complications reported in the present article were examined by me personally, and I was able to make no distinguishing classification between the various forms that appeared; in fact, the process seemed to me similar in every one of the cases, the more severe cases going on to a bronchopneumonia, the less severe stopping with a temporary bronchitis or pleurisy. The onset was similar in all the cases. The average time of onset was three days, whether all the cases be taken collectively or each of the three separate types individually. There was no case which resembled an infarction, and I did not observe the close resemblance to thrombosis and embolism pointed out by Homans in some of his cases.

One of the cases which died of pneumonia in the series of 2,000 cases cited above taken from the Free Hospital records previous to the present series closely resembled the type of case described by Homans as embolic. I did not see the case personally, but from the history I should unquestionably classify it thus. An additional reason for this case to be regarded as of the embolic type is that pneumonia occurred in a very septic patient during the month of June at a time when post-operative pneumonia of the ordinary type is comparatively rare.

One of the most striking factors that appears in the study of these cases, and one that is observed by all writers of the subject, is the occurrence with rare exception of post-operative pneumonia only in the cold weather months, that is, from November to April. The possible bearing of this factor on the causation will be referred to later. Another constant observation in the study of post-operative pneumonia is that, in patients having a tubercular or bronchitic focus in the lungs, the process is almost invariably lighted up. This is a most important fact and is at once suggestive of the possibility that the irritative action of ether on the normal respiratory tract has little, if any, deleterious effect, but that where there exists at the time of operation an inflammatory focus in some portion of the bronchi or lung, the irritative action of the ether may be sufficient to light it up into a more extensive and serious process. This theory has considerable support in the fact that post-operative lung complications occur almost universally in the cold weather months at a time when non-operative bronchitis and pneumonia are most common. Dr. Munro states in his article that the post-operative lung complications may be merely a matter of chance. Is it not reasonable to agree with him that it is a matter of chance, and that this chance is a pre-existing focus of infection, which might or might not have developed into a more extensive process, but which receives an added stimulus from the irritative effect of the ether? It is not unlikely that many of the cases of post-operative pneumonia had local foci, which might have been detected by expert examination before operation. It must be conceded that the physical examination of the lungs in public hospitals made as a routine before surgical operations is not usually of the expert or even of the careful type. The number of hospital cases who during the winter months develop bronchial colds while waiting for operation supports also to some extent the reasonableness of this theory. These cases, if operated on immediately on entrance to the hospital, before the bronchial affection had made itself evident, would be recorded as cases of post-operative lung complication when the bronchial cold did develop. Considering the effect which ether has on a previously tubercular or bronchitic process, it may well be conceded that in a case like the one just cited, especially if the patient were septic or old and feeble or desperately sick from some other cause, with a resultant lowering of resistance, ether might stimulate to a serious condition of bronchopneumonia a local focus of infection which might under other circumstances terminate only in a bronchial cold.

The theory that post-operative lung complications are commonly caused by the stimulation of pre-existing foci of infection in the lungs is well illustrated by two cases taken from the series of 2,000 cases preceding the series which forms the subject of this paper. The first case is one whose entrance examination of the lungs is recorded as negative. This patient developed a pleurisy soon after the operation. Several months later she died of tuberculosis of the lungs, though apparently well when she left the hospital. One is

inclined to believe that this patient's death was ultimately due to the lighting up of a pre-existing tubercular focus, which might possibly have been detected before the operation. The second case was one who on entrance to the hospital had a well-marked bronchitis. Operation was deferred until it was supposed that she had recovered. A lobular pneumonia developed two days after the operation, from which the patient recovered. This is a most striking example of the way in which an ether anesthesia may light up a pre-existing bronchitic infection, for it is perfectly obvious that the patient had not completely recovered from the bronchial cold from which she was suffering on entrance to the hospital.

There is still one other important factor which appears in all reports on this subject, namely, the greater occurrence of post-operative complications in abdominal operations. The Free Hospital series shows a difference of 10 to 1 in frequency over non-abdominal operations, while Risley's report shows a difference of more than 4 to 1. Operations which require considerable handling of the gut figure prominently in all the post-operative pneumonia reports, especially in that of Risley. This greater frequency of post-operative pneumonia in cases of abdominal section may be used as a further argument in our theory of causation. It is sufficiently well known that the reflex respiratory irritation from ether is much greater during laparotomies than during other operations not laparotomies, and especially in cases where there is considerable handling of the gut or injury to the peritoneum. Abdominal cases not only require more ether, but a more forced administration. In a case, therefore, of a pre-existing focal infection in some part of the bronchial tract, a greater irritative effect by the ether on this infected focus would be exerted during a laparotomy than during an operation elsewhere.

A comparison of the Free Hospital cases with the classified cases taken from Homans's article would show that post-operative pneumonia is less frequent following pelvic operations than it is after operations performed higher in the abdomen. The highest percentage of occurrence seems to be following operations that are performed near the diaphragm. The theory has been advanced that the greater occurrence of pneumonia after these operations is due to an infection which takes place directly through a system of lymphatics which has been demonstrated as existing between the abdominal and pleural cavities. It seems to me more reasonable to assume that in operations near the diaphragm there is greater irritation of the respiratory tract.

It is possible that the excellence of the Free Hospital figures may partly be due to the extremely careful preparation which all laparotomies receive before operation. By this preparation, which begins two days before the operation, every patient, unless an emergency case, comes to the operating table with the intestines almost completely collapsed, and the packing off of the intestines necessary for pelvic operations is comparatively simple and can be done with a minimum amount of gauze. In this way there is no forcible handling of the intestines, and only a small part of the intestinal peritoneum comes in contact with the irritating surface of the gauze sponges. Etherizers are instructed to have their patients deeply anesthetized immediately before the packing off of the intestines, a process which, if done with the patient partially anesthetized, causes a great amount of reflex irritation and much violent handling and pushing of the intestines. In order to insure the perfect anesthesia of the patient before the surgeon makes his incision, all the table preparation is done with the patient in the Trendelenberg position. If this is not done, the sudden turning of the patient into the Trendelenberg position is liable to start up an irritating reflex of the respiratory tract.

CONCLUSIONS.

1. Post-operative lung complications occur somewhat more frequently and are more fatal in cases previously septic or desperately sick or in the aged and feeble.

2. Operative shock, method of administration, length of time of the anesthesia, age of the patient unless extreme, physical type of the patient, bad behavior under ether, wound sepsis, pulmonary embolism, do not seem to bear any constant relationship to the causation of post-operative pneumonia.

3. Post-operative pneumonia and bronchitis occur with great constancy during the cold weather months, and are rare during the summer months.

4. Pre-existing foci of infection in the lungs are almost invariably lighted up or aggravated by operations under ether anesthesia.

5. The following theory of causation is suggested by the writer. Most of the cases of post-operative lung complications are caused by the lighting up or the aggravation of pre-existing focal infection.

6. Many post-operative pneumonias might be avoided by a more careful and more expert pre-operative examination of the respiratory tract.

AN ANALYSIS OF SEVENTY-TWO CASES OF PNEUMOTHORAX.

BY JAMES B. AYER, M.D.,

Assistant Visiting Physician, Long Island Hospital, Boston.

In 1900 the cases found in the medical catalogue of the Boston City Hospital for the previous eighteen years were analyzed,[1] and it is instructive to compare these cases with similar cases from the same services during the succeeding ten years, from which I have collected in a similar manner 55 cases, and have added 17 others from the surgical, x-ray, contagious and autopsy records.

As the services are not greatly larger now than when Dr. Morse's statistics were collected (averaging about 150 on the medical services), it is evident either that the condition of pneumothorax occurs

[1] John L. Morse: An Analysis of Fifty-One Cases of Pneumothorax. Am. Jour. Med. Sci., May, 1900.

more frequently, or that the diagnosis is more often made; as tubercular cases in which pneumothorax especially occurs are now *non grata* at this institution, it would seem that the increased number of such cases is probably due to their more frequent recognition; and in the detection of them, the x-ray examinations have played a considerable part, as will be seen.

The cases of pneumothorax naturally fall, according to etiology, into two large classes, which may be tabulated as follows:

I. Tubercular cases,		41
II. Non-tubercular:		
Empyema,	10	
Pneumonia,	4	
Pleurisy with effusion,	3	
Pleurisy ?,	1	
Diphtheria, subcutaneous emphysema, pneumonia and pneumothorax,	1	
Echinococcus disease,	1	
Subphrenic-intrathoracic abscess,	1	
Traumatic,	8	
Unknown cause,	2	
		31
		72

TUBERCULAR CASES.

Of 41 cases here classed, 30 were proved either by finding bacilli or at autopsy; 11 seem almost certainly to have been tubercular from onset, symptoms, course or signs. Of these 41 cases, however, we must for a time dispense with 12, as these either had been aspirated before admission or showed no signs of pneumothorax until after tapping.

Sex. — Of these 29 cases of spontaneous pneumothorax in tubercular or presumably tubercular subjects, all except 2 were men.

Age. — The average age was thirty and one-half years, the two women being slightly younger. The youngest was two years; the oldest, sixty-three; but both of these stand at their respective ends of life; nearly half were in the twenties.

Nativity. — As would be expected, the majority of these patients were born in New England or in Ireland, though six other countries are represented.

Occupation. — Many occupations are represented. Sixteen may be said to have been engaged in indoor pursuits, 13 outdoors, at the time of onset.

Location. — As in other series, we find a considerable majority of left-sided cases, 18 being on the left, 9 on the right, 2 not stated.

Prodromal symptoms. — The majority give a history of less than six months' illness. This may be of importance in view of the fact very frequently noted by others, and found in all of these autopsies, that pneumothorax occurs where there are few adhesions. In 3 cases there had been so little constitutional disturbance that they claimed to have been " always well " prior to the onset of pneumothorax.

Onset. — Though in some cases it is impossible to distinguish symptoms of pneumothorax from symptoms of associated pleurisy, in most it is fairly evident. In 5 cases pneumothorax came on insidiously without marked symptoms, or onset was masked by the chronic tubercular process, In the other 24, onset was sudden. The records do not go into what the patients were doing when the pneumothorax occurred, but as the great majority were sick at the time, most were doubtless doing little muscular work; it is specifically stated that in 3 cases the patient was waked from sleep by dyspnea and pain. *Intense pain* and *dyspnea* are by far the most common symptoms, the two appearing together, singly or in combination with other symptoms given below, and in almost all cases associated with the ordinary symptoms of pulmonary tuberculosis.

These prime symptoms as recorded occurred in the following frequency in the 29 cases:

I. Acute symptoms: Pain, 17; dyspnea, 16; weakness, 4; chill, chilly, followed or not by fever, 4; expectoration of large amount of pus, 2; palpitation, 1; dizziness, 1; diarrhea, 1; vomiting, 1.

II. Insidious onset. Symptoms of advancing tuberculosis. It is especially noted that 3 patients had no pain at onset.

Physical signs. — The hospital records, written by so many men, and of so varying quality and fullness, do not allow of an analysis of the signs; such would only add confusion to the paper. In reviewing the records, all diagnoses have been rigidly questioned and several cases omitted in which the possibility of cavity could not be excluded, most emphasis being placed upon succussion, dislocation of heart incommensurate with the amount of fluid present, x-ray, paracentesis and autopsy findings, together with, of course, the less dependable points, — hyperresonance, diminished and absent fremitus and breath sounds, amphoric breathing and metallic tinkle.

The treatment and outcome of the cases will be taken up together with the next group.

TUBERCULAR CASES IN WHICH PNEUMOTHORAX WAS OR MAY HAVE BEEN ARTIFICIAL.

Age. — Average, thirty-eight (twenty-two to sixty-five years).

Sex. — Nine males, 3 females.

Location. — Contrary to the usual rule, the right side predominates with 7, against 5 on the left.

Prodromal symptoms are very similar to the rest of the tubercular group: Seven had had cough for six months or less; 2, cough for a year; 1 had not been well since " grippe " sixteen months before; 1 had a tubercular testicle; 1 had had no prodromal symptoms.

On close examination of the records it was found that 5 of these cases certainly did not have pneumothorax until after tapping. One case had signs of either cavity or pneumothorax before, definite signs of free air after, tapping. The other 6 cases entered the hospital after tapping outside and showing at entrance free air in the chest. In one of these cases the patient felt succussion immediately after aspiration. So that, of these 12 cases, in at least 6 of them pneumothorax was associated with tapping. We shall deal with this subject later in the paper.

Treatment and outcome of 41 tubercular cases. —

In order to intelligently analyze the treatment and results thereof, we must classify them.

Serous cases treated by paracentesis. — Of 5 such cases, 4 were discharged relieved. The other died of pulmonary hemorrhage. One of the discharged cases is known to have died since.

Pus cases. — Eight treated by paracentesis; 4 died within five weeks of admission to hospital; another is known to be dead five years later; 2 were discharged relieved and 1 much improved.

Thirteen were operated upon, by either incision, resection or excision of rib. Of these, 1 died on the table, 5 died within five months and 1 in a year; 3 others were discharged in a very serious condition. The other 3 were discharged relieved, with some hope of improvement; unfortunately, we have not been able to trace them since.

Air case. — Died within a few hours of the onset of pneumothorax in spite of insertion of needle twice.

Physical signs of air and fluid not aspirated. — Of 11 cases, 3 died soon after entrance; 3 were discharged not relieved and must have died soon; another is known to have died two years later; 4 were discharged relieved.

Three cases, not stated.

One may ask what the pneumothorax had to do with the deaths. In only one case — from the hospital records and from return letters — can we definitely charge pneumothorax with the immediate cause of death; this was a man who died a few hours after its onset and who never recovered from the sudden onslaught. How much deleterious effect pneumothorax has is a matter for individual opinion in each individual case.

One might think that in those cases where air was supposed to have been artificially introduced the outcome might be brighter. Not so; of the 7 cases most suspicious in this respect, 2 died, 1 was discharged moribund; only 4 were sent out relieved. In only 1 case was the air found to have disappeared before discharge from the hospital.

From the above results of treatment, and from records of other observers, it is difficult to speak dogmatically concerning the treatment of tubercular pneumothorax. The best rule seems to be: If there is fluid, draw it off; if clear, repeat as often as necessary, and if purulent, drainage offers the best chance.

AUTOPSIES: TUBERCULAR CASES.

Several important points were noted in the 6 cases which came to autopsy:

(1) In every case pneumothorax was associated with cavity-formation in the lung of the same side.

(2) In 3 of these was a communication found between cavity and pleura.

(3) In 5 cases there was tuberculosis of both lungs, and in 4 of these was there evidence of an older process or denser pleural adhesions on the opposite side, i. e., pneumothorax occurred on the side where the process had evidently advanced most rapidly. This is confirmatory of others' observations.

(4) In 3 of the cases there was tuberculosis elsewhere: in one case in the bones of the fingers, in another in adrenals and prostate, and in a third, general miliary tuberculosis.

NON-TUBERCULAR CASES.

Empyema Following Pneumonia.

Ten cases of pneumonia developed pyo-pneumothorax; of these, 8 were certainly not artificially produced and will first be considered.

Six were men, 2 women; the average age was twenty-six years, varying from eleven to thirty-seven. Of 5 cases where there is good history of an attack of pneumonia, the complication of pyo-pneumothorax was probably first recognized on an average only after fourteen weeks from the date of pneumonia, as these cases came to the hospital untapped. No symptoms suggesting the onset of pneumothorax was given in 4 of these, but the fifth developed it during a severe coughing spell in the hospital, during which he raised a "half basin" full of pus; one of the others came to the hospital coughing large amounts of dark foul pus, evidently from a lung abscess.

Beside the 5 cases with evident history of recent pneumonia, are here grouped 3 others: 1 gave indefinite history of pneumonia twelve days before; another had fallen into the water, — at first seemingly well, he had later come to the hospital with pneumonia, after which signs of fluid developed and later still air, death occurring one month after immersion.

The eighth case of this series was a striking one. Though "well at the time," he had six days previous to admission become suddenly completely exhausted and unconscious. On recovering consciousness he complained of right-sided pain and dyspnea. At entrance there were signs of pneumothorax only, but a week later pus was found on tapping, containing pneumococci, and a few days later still thoracostomy was performed. At first the case went well, then irregular temperature for a week, when suddenly a second attack of dyspnea and cyanosis supervened and examination showed air in the left chest also. In spite of a discharging empyema on the right, and pneumothorax on the left, the patient lived twelve hours. Post-mortem section showed double empyema, but on neither side could a pleuro-pulmonic fistula be demonstrated even on filling the lungs with air under water.

Besides the 8 cases above were 2 others, one of whom had been tapped three times before admission and showed pyo-pneumothorax at entrance, dying soon after; the other showed typical signs of empyema on admission, but immediately after tapping, air was found also. This case died shortly after resection of a rib.

To sum up. — The symptoms at onset in these 10 cases were not acute in 3, but were part of the picture of neglected empyema. Of the 3 with acute onset, 2 consisted of the raising of a large amount of pus, evidently by establishing a broncho-pleural fistula. Only one exhibited acute dyspnea and pain so characteristic of the tubercular series. The explanation seems at hand: Doubtless in the majority of cases empyema alone

had rendered the lung on that side practically useless and had gradually pushed the heart to the other side of the chest. Pneumothorax in this case would be more likely to relieve than aggravate pressure; in the sudden pneumothorax from rupture of a tubercular cavity, however, respiratory and circulatory equilibrium are suddenly changed to the disadvantage of both heart and lungs.

Result of treatment. — Operative procedures were undertaken in 9 cases, resection of a rib under ether being the favorite. Four died directly, 3 being very sick at the time of operation, the fourth dying as described above from development of double pyo-pneumothorax. The other 6 were discharged relieved. In 3 the discharge was noted to be nearly stopped within two months; in 1 it continued at nine months; 2 cases have replied to inquiry that they are well after five and seven years respectively.

Pneumothorax, then, supervening in empyema following pneumonia, we cannot look upon as an evil except rarely, and it seems at times beneficial; its treatment is that of the accompanying empyema.

What the cause of pneumothorax in empyema is aside from the cases where a connection has been made with the lung is hard to say; some have attributed it to gas-producing organisms.

PNEUMONIA.

Four cases, but 3 of them surely followed tapping. In one case after the second tapping for hydrothorax, succussion was heard, no serious symptoms intervened and when the patient left the hospital two weeks later neither fluid nor air was demonstrated. A second case was aspirated, a sterile bloody fluid withdrawn and pneumothorax appeared; at discharge three weeks later there were signs of fluid, but the air was thought to be slight in amount.

In a third case paracentesis had been performed on two occasions and nothing obtained at either time; nine days after the last tapping the fluoroscope showed localized, probably encapsulated, pneumothorax. Before discharge there is a note that the pneumothorax had decreased. The fourth case was operated upon for appendicitis, after which pneumonia declared itself and also pneumothorax. At autopsy twenty or thirty bubbles of air escaped from the right pleural cavity, but its origin could not be explained. It is interesting to note that in this last case the pneumothorax though so slight in amount was diagnosticated before death.

Pleurisy with Effusion.

Three cases, the air following tapping in the hospital in 2; the third had been aspirated before admission and showed pneumothorax when first seen. In 2 air had disappeared after six weeks; all were discharged relieved, one, however, succumbing three months after leaving the hospital.

The two following cases seem designed to show us two methods of artificial pneumothorax:

Pleurisy?

A man twenty-five years of age complained two days before of sudden pain over his entire abdomen and especially the right lung. At entrance the lungs were found normal; later, however, a small patch of dullness was found near the right base and a needle was twice inserted, whereat signs of pneumothorax appeared. Both taps were "dry." For three weeks the signs of air persisted and then disappeared; no fluid was at any time demonstrated. The patient was discharged absolutely well with lungs normal. The course was not that of pneumonia.

Diphtheria, Subcutaneous Emphysema, Pneumonia, Pneumothorax.

A boy of ten developed severe laryngeal diphtheria with subcutaneous emphysema of neck and back, and was intubed. Pneumonia set in on the right and the emphysema became constantly more marked; exploratory puncture brought away no fluid, but immediately after tapping pneumothorax appeared. Two more tappings brought away 23 and 19 oz. of air respectively, but death occurred eight days after the first paracentesis. Autopsy in this case showed broncho-pneumonia in both lungs, and on opening the right pleural cavity much air escaped. There was no mention of the origin of the pneumothorax at autopsy, which probably was introduced from without, though the possibility of its coming from the subcutaneous emphysema must be kept in mind.

In reading over the case reports of the above 9 cases it is difficult not to believe that the air was introduced into the chest in some way during the process of tapping in 8 of them; if not, it is very hard to explain its presence. Moreover, in 7 of these we are struck with the fact of its disappearance in a moderate length of time, in spite of the fact that the pleura must have been anything but normal in any of them.

We now have to report 2 rare cases of pyo-pneumothorax, though the first one may possibly be of artificial origin:

Echinococcus Disease.

A carpenter, born in Italy, age not given, had been "feeling badly" for some time. Two weeks before admission he had severe pain in the back of his chest, but no cough. Examination showed signs of fluid in the right chest, but aspiration was unsuccessful and the patient asked for his discharge, signs in the chest remaining as at entrance. On his return to the hospital two weeks later he stated that he had been tapped a few days after leaving the hospital and that a half pint of clear fluid had been withdrawn. Signs now were typical of fluid and air. Paracentesis this time was successful, drawing off 5 ccm. of thick bloody pus. He was immediately turned over to the surgeons, who excised a rib and drained; soon after they were surprised to see in the pus and in the sputum also echinococcus cysts. Convalescence was extremely slow and he was at last discharged a chronic invalid to another institution.

Emerson [2] was able to find reference to pneumothorax in hydatid disease in the case of only three authors representing four cases. Unfortunately, we cannot here be sure that pneumothorax was not an accessory condition.

Subphrenic-Intrathoracic Abscess.

A man of thirty-six, with no previous history given, complained of a sharp pain in the epigastrium the day before admission, for which morphine was required. At entrance there were contradictory signs of fluid at the base of the right lung. In six days, however, there was undoubted fluid at this point, shifting readily with change of position, x-ray showing air and fluid. On the tenth day from the first symptom he was tapped and air and over a pint of pus withdrawn; later resection was performed; a finger introduced could feel a perforation in the diaphragm. The pus showed a variety of organisms.

The patient died the day of operation and no post-mortem examination was allowed; the etiological diagnosis is, therefore, not certain, but it would seem to be due to perforation of a hollow viscus as the lung was not demonstrably affected; gastric ulcer with perforation and extension of accompanying abscess is the author's first choice in this case.

Traumatic Cases.

There were 8 such patients, 5 being run over by teams, 3 from stab wounds, and withal only one death. In 4 of the 5 crush cases (the fact is not mentioned in the fifth), though it is difficult to think that the team did not run over both sides of the chest, pneumothorax appeared on the left, a fact of possible significance.

The signs can hardly be summarized from the records, but a number of data are significant. Concerning the onset of fluid, one man whose chest had been tapped with a hatpin four hours previously already showed signs of air and fluid; this rapidity of fluid accumulation was not duplicated by any other case and perhaps was aided by the alcoholic state of the patient. In two days the fluid was largely gone, and this in spite of the fact that the man developed delirium tremens.

Another case showed air the day of accident, and fluid and air by x-ray in two days. But other cases gave evidence of fluid only after a week as a rule. As for the duration of pneumothorax and complications, several patients were discharged almost immediately, with air present. In 2 women who developed pyo-pneumothorax, thoracostomy was performed, the discharge in each case having almost ceased in seven weeks, when released from the hospital.

In 2 of the crush cases it is stated that no evidence of fracture could be found, one four and one-half, the other twenty-seven years of age.

Subcutaneous emphysema occurred in 1 case, but apparently was not a troublesome complication.

[2] Emerson, C. P.: Johns Hopkins Hosp. Rep., 1903.

Cases of Unknown Origin.

One, a man seventy-four years of age, with indefinite signs of pulmonary disease, developed pneumothorax under observation, but without accompanying symptoms of any consequence. He died the same day as operation.

A second man, thirty-nine years of age, came to the hospital with signs of air and fluid in the right chest. On aspiration no fluid was obtained, but subcutaneous emphysema developed. Before a positive etiological dignosis could be made he left against advice.

PNEUMOTHORAX ARTIFICIALLY PRODUCED.

What is now said may seem to some to throw discredit on the institution, the records of which are here published. After a careful reading, however, we feel that the very considerable number of cases placed under this heading is correct. The fact that most authors omit discussion of artificially produced pneumothorax is no argument that it did not exist in their series. In Emerson's series, 20% were considered as in this category, which corresponds fairly with our 19% of certain and 32% of possible artificial origin.

From the above records the following are considered as artificially produced:

	Surely.	Possibly.
Of 41 tubercular cases,	6	6
Of 10 empyema cases,	1	1
Of 4 pneumonia cases,	3	
Of 3 pleurisy with effusion cases,	2	1
Of 1 pleurisy ? case,	1	
Of 1 diphtheria with subcutaneous emphysema case,	1	
Of 1 echinococcus case,		1
	14	9
Total,		23

In most cases our criterion consists in finding signs of pneumothorax after tapping in the hospital, where had been no signs before, examination being frequently supported by x-ray findings; occasionally the x-ray alone was relied upon. In one case were taken the symptoms of the patient who felt succussion immediately after paracentesis.

It is noticeable that in no case of pneumothorax were symptoms urgent, as was so frequently the case in spontaneous pneumothorax. This may be due to the fact that the act of paracentesis was itself an annoying performance and so extra discomfort passed unnoticed.

Nor was artificial pneumothorax the immediate cause of death in a single case. In one, however, it doubtless had some influence. Only one such case came to autopsy, and in this the record does not explain the cause.

This leads us to the method of causation of pneumothorax in these cases. The usual method of tapping in this hospital has been with the ordinary aspirating bottle, with suction pump, connected with a needle by a "push" joint; occasionally, however, a one-piece apparatus with gravity suction has been employed, and for diagnostic purposes at times a syringe with needle attached. We have not seen a needle or trochar

employed without some suction contrivance. With the above forms of apparatus it is conceivable that air may be pumped in, though this would probably give much more acute symptoms than any of our cases admit; also air may be introduced if the connections are broken or are insecure, and this seems a very likely method; also undue or even slight suction might well cause rupture of a superficial cavity, especially if associated with cough, as is frequently the case near the end of tapping. Then again the chance of introducing air into the pleural cavity from subcutaneous emphysema is a possibility which the case of diphtheria with this complication suggests, and of course we must always bear in mind the possibility of scratching the visceral pleura.

Although we cannot accuse artifical pneumothorax of immediately fatal results, or even be sure of its remote ill-effects in more than one or two cases, yet we cannot feel that it is a desirable thing to let non-sterilized air into the pleural cavity from without, or cause an internal open or closed pneumothorax by connection with a cavity or even with healthy lung.

The greatest care, then, should be taken in aspirating, first, that neither too great nor too sudden negative pressure be produced; second, that the apparatus be not disconnected during the process of tapping, without suitable stopcocks.

To this end an instrument devised by Dr. Francis H. Williams some twenty-five years ago appeals to the writer as simpler and safer than the ordinary aspirating set, with its uncertainty of connection and amount of suction; to which advantages may be added those of greater compactness and cheapness. This apparatus consists of three pieces of stiff rubber tubing, one end bearing the hollow needle, another leading to a small reservoir above to be filled with sterile water, and the third falling almost to the floor, the three attached in the center to a stopcock capable of uniting any two of the tubes. Thus by proper manipulation a chest may be aspirated by the constant suction of syphonage; by improper handling, harm would be unlikely to result.

Where a very little fluid is required for diagnostic purposes only a needle already attached to a 1- or 2-oz. syringe may be even simpler than the above.

X-RAY EXAMINATION IN PNEUMOTHORAX.

It is not my intention to speak at length on the value of x-ray examinations in pneumothorax, but merely to report in a general way its bearing upon the above cases (for technical considerations see Williams: The Roentgen Rays in Medicine and Surgery).

We have at hand 51 records of x-ray examinations in pneumothorax, representing 34 cases (of these 31 fall in this series, 3 are of previous date). The examinations are mostly fluoroscopic, some are radiographic. These examinations represent the work of Drs. Francis H. Williams and S. W. Ellsworth.

A summary of the service done by the x-ray in the 34 cases may be presented as follows:

	Cases.
Diagnosis of pneumothorax established first by x-ray examination,	12
Diagnosis of pneumothorax confirmed by x-ray examination,	19
Pneumothorax denied by x-ray, found on tapping,	1
Agrees with physical examination showing no air (pneumothorax appeared later),	1
No diagnosis made,	1
	34

In 3 examinations unsuspected fluid was found accompanying pneumothorax. In at least 2 cases the localized or encapsulated character of the pneumothorax was determined. In several cases it was useful in determining the amount of expansion of the lung on the affected side after operation.

A word as to the signs considered most reliable in x-ray diagnosis of pneumothorax: (1) Heart displacement, present in every case except 2 of 25 cases where the point is noted; (2) increased radiability of lung, to be distinguished from emphysema and cavity, especially significant when associated with readily changing surface of fluid if present; (3) visual fluid wave, either on shaking or with the heart beat; (4) diminished or absent diaphragm movement on the affected side and a low position of the same.

Doubtless in this series of cases the x-ray has been of valuable diagnostic and prognostic service, in leading either to an earlier or a more accurate understanding of a given case. The number of cases determined first by x-ray seems large; doubtless many of these were considered probably pneumothorax from physical examination, but it was just this doubt between pneumothorax and cavity, between increased pulmonary resonance above fluid and pneumothorax, which the x-ray examination was at times able promptly and decisively to dispel.

TOTAL NUMBER OF CASES OF PNEUMOTHORAX AT THE BOSTON CITY HOSPITAL IN TWENTY-EIGHT YEARS.

For the sake of completeness, let us add Dr. Morse's cases to ours with reference simply to etiology. The table stands as shown on the following page.

This table represents all classes of hospital records as far as could be determined in the past twenty-eight years. Doubtless a number of cases have escaped the cataloguer, as frequently only one diagnosis is indexed and pneumothorax is often not of the greatest importance.

SUMMARY AND CONCLUSIONS.

Tubercular cases comprised 69% of all cases of pneumothorax at the Boston City Hospital in twenty-eight years. Most were young or middle-aged men, and most had a recent history of less than six months' illness. The left side was most often affected.

Pain and dyspnea were by far the most common symptoms at onset, as also in Dr. Morse's series.

	Dr. Morse.	Author's.		
Tubercular cases,	36 8(?)	41		85, or 69%
Non-tubercular cases:				
Empyema or abscess following pneumonia,	4	9	13	
Immersion,	1	1	2	
Pneumonia,		4	4	
Pleurisy with effusion,		3	3	
Pleurisy ?,		1	1	
Diphtheria, subcutaneous emphysema and pneumonia,		1	1	
Echinococcus disease,		1	1	
Subphrenic-intrathoracic abscess,		1	1	
Traumatic,	1	8	9	
Unknown,	1	2	3	38, or 31%
				123 cases

A number of acute symptoms were less frequently of prime importance.

The treatment in these cases was for the most part essentially that of the fluid present; the prognosis was anything but encouraging.

Autopsy showed cavities in all 6 of our cases, and 8 out of 10 of the older series. Of the 16 autopsies the perforation was found in only 9, good evidence that the opening is apt to be very small, as, in fact, it almost always was when found. Pneumothorax seems most frequently to occur on the side of a rapidly advancing process where adhesions are either absent or friable. The other lung and other parts of the body are apt to show long-standing tuberculosis.

Pneumothorax may follow a long-standing empyema (of three months or more duration), by establishing a pleuro-pulmonic fistula or other means as yet not understood. The onset in these cases does not usually show the acute symptoms so characteristic of the tubercular cases, but may even cause temporary relief. Operative treatment in these cases is frequently permanently successful.

Two rare cases are here reported, that from subphrenic-intrathoracic abscess and that due to echinococcus, if the latter was not artificial in origin.

In traumatic cases we see fluid developing rapidly; the air does not, as a rule, last long and is probably of no serious import.

Artificial pneumothorax occurred in 19% and possibly in 32% of our cases. Though agreeing with some other series, this is altogether too high a percentage. By use of a simpler and safer instrument than that commonly employed, we feel that artificial pneumothorax, although its occurrence is in many cases probably of no ill consequence, could be largely avoided.

X-ray examination has frequently made difficult cases clear, rendered diagnoses more exact, qualified prognosis and explained the effect of treatment. Since this form of examination has come into more constant use in this hospital, pneumothorax has been more frequently diagnosticated.

I wish to thank all of the physicians and surgeons under whom these cases occurred for their kindness in allowing of their publication.

In particular thanks are due Dr. Francis H. Williams, at whose suggestion and by whose helpfulness the above statistics were compiled.

Clinical Department.

APPENDICITIS DURING THE YEAR 1908–1909 AT THE MASSACHUSETTS GENERAL HOSPITAL.

BY G. G. SMITH, M.D., BOSTON,
Assistant in Anatomy, Harvard Medical School.

Professor Kümmell's article on appendicitis in the *Archiv für Klinische Chirurgie* for June, 1910, reviewed in this Journal for Aug. 11, 1910, aroused my interest in the statistics of appendicitis. I looked up, therefore, all cases of appendicitis which were operated upon at the Massachusetts General Hospital, Boston, during the year beginning Nov. 1, 1908. This period was selected because the cases were fully catalogued only up to December, 1909.

There were in all 513 cases, divided into three groups — acute, subacute and chronic. The acute cases included all those requiring prompt operation, and usually presented those symptoms of pain, local tenderness, fever and leucocytosis which form the picture of "acute appendicitis." The subacute cases were, in the main, cases which had entered the hospital because of continued mild disease of the appendix, but were in no sense emergencies. The chronic cases were partly also of this type, and partly were discovered during operations upon the pelvic organs, especially in women.

In the subacute and chronic classes, appendectomy was done two hundred and sixty-eight times. The only death was in the case of an injured man who had sustained rupture of the small intestine, followed by peritonitis. At operation, the appendix was found to be coated with fibrin and was removed before the rupture was discovered. Since death in this case was in no sense due to the removal of the appendix, we are justified in saying that in 267 simple appendectomies there was no death. This was in spite of the fact that, in February, 1909, 3 cases contracted post-operative pneumonia. Of the 268 cases, 114 were in males, 154 in females. Only a few cases were drained, and those because of leakage from broken adhesions.

There were 246 acute cases, of which only 30 were treated without drainage. Only 76 of this class were in women; 170 in men. Twenty-eight cases were below ten years of age, the youngest

being two; 124 were between ten and twenty-five; 55 were between twenty-five and forty; over forty were 39, the oldest being seventy-three. This group has been rather arbitrarily divided into cases with peritonitis, cases with abscess, and simple acute appendicitis. Cases with peritonitis were those in which there were no walling-off adhesions, and in which the pus appeared to be spread over at least a third of the abdominal cavity. No case was considered to have an abscess unless a definite pocket of pus had been found. If the main process had been walled off, but a cloudy serum appeared on opening the peritoneum, the case was put into the abscess class.

Many of the simple cases presented fibrin upon the appendix, and free fluid, but they were not classed as peritonitis or abscess. Their usually speedy recovery (twelve to eighteen days) proved the absence of a more severe infection.

Of 246 cases of acute appendicitis, 66 were of the simple type. Of these, 36 were drained; there were 3 deaths (4.5%). One death followed pneumonia; one, pylephlebitis, and the third was in a case in which the colon had been resected at the same time the appendix was removed. One hundred and thirty-five cases showed frank, walled-off pus at the time of operation, and of these 10 died, a mortality of 7.4%. All but one of these died as a result of some complication. One had pneumonia; one, a probable pulmonary embolus; one, a hemorrhage from the wound; two, intestinal obstruction; and four, general peritonitis.

There were 45 cases in which, at operation, peritonitis, more or less general, was found. Of these, 10, or 22%, died. One had obstruction, 1 erysipelas, 2 pneumonia; the remaining 6 died apparently from the toxemia of their peritonitis.

Of the 23 deaths from acute appendicitis and its complications, 1 was in a child of eight, 7 were in people of from ten to twenty-five years, 4 in those of twenty-five to forty, and 11 in those above forty years. When arranged to show the relative mortality of the different ages, these figures are as follows:

	Cases.	Deaths.	Per Cent.
Below 10 years,	28	1	3.5
Between 10–25 years,	124	7	5.6
Between 25–40 years,	55	4	7.2
Between 40–73 years,	39	11	28.

From the above figures it is seen that acute appendicitis is more than twice as prevalent in men as in women; that between the ages of ten and twenty-five as many have the disease as in all other ages put together. It seems allowable to predict that, barring complications, there may be no fatal results following appendicitis without abscess or peritonitis; and to say that youth is a definite factor in recovery.

THE SHOOTING OF SALVATORE MIRANDO.*

BY J. WINTHROP SPOONER, M.D.,

Late Medical Examiner, Hingham, Mass.

SALVATORE MIRANDO was an Italian, aged about twenty-one, and had lived in Hingham for several years. On Sunday morning, Aug. 22, 1909, he visited a settlement of Italians on the estate of Thomas W. Lawson, of Scituate. The object of his visit was said to be to raise money to aid another Italian who had got into trouble and was under arrest. Mirando was engaged in conversation with one of Mr. Lawson's men, whose name could not be ascertained. The two men very soon were quarreling, and a hand-to-hand scuffle ensued, in which Mirando threw the other man into the bushes. The latter immediately rose and, drawing a revolver, shot Mirando in the upper anterior portion of the left chest. Mirando turned at once and ran a distance of sixty feet when he fell forward on the ground dead.

Autopsy, twenty-four hours later, at place of death.

Young man, well dressed, front of shirt and undershirt saturated with blood. Rigor mortis well marked. Lividity of dependent parts. Two fingers' breadth below the middle of the left clavicle, slightly inside the nipple line, is a perforating wound ½ inch in diameter, surrounded by a black lacerated area, the whole being ¾ inch in diameter and surrounded by a red areola. The wound penetrated the chest in the first intercostal space. On opening the thorax it was found full of liquid blood and currant jelly clots.

On the anterior aspect of the upper lobe of the left lung, midway between the apex and its lower border, near the internal edge, was a lacerated wound surrounded by a hemorrhagic area, the whole being ¾ inch in diameter. The mediastinal tissues in the neighborhood were blood-stained and boggy. The wound passed through these and through the ascending aorta just below the arch. Thence the wound is traced through the right lung, entering on the internal surface one third of the distance from the apex to the lower border of the upper lobe, passing out of the posterior surface of the lung, and out of the thorax between the fourth and fifth ribs. Here was found blood-stained tissue and fragments of the fourth rib. Thence backwards and upwards the wound is still traced through the blade of the right scapula, and among the fibers of the infraspinatus muscle is found a flattened bullet. With the exception of an old inflammation about the appendix, the abdominal organs were in a healthy condition. The heart and lungs were free from signs of disease.

The only noteworthy point which has led me to report this case is that a man who had been shot through the ascending aorta, receiving a wound large enough to cut one third of the vessel, should be able to run a distance of sixty feet.

The shooting took place early on a Sunday morning, in a very secluded spot, a long distance from the highway or from any human habitation, so that it was several hours before the police had notice of the case. The officers of Scituate began a diligent search for the perpetrator of the deed. Authorities of Boston as well as those of the towns adjoining Scituate were notified, but in spite of their efforts the person who shot Salvatore Mirando has never been apprehended.

* Read before the Massachusetts Medico-Legal Society, Feb. 2, 1910.

Medical Progress.

REPORT ON PROGRESS IN OTOLOGY.*

BY HARRIS PEYTON MOSHER, M.D., BOSTON.

(Concluded from No. 12, p. 477.)

OTITIS MEDIA AND THE GENERAL PRACTITIONER.

SCHWARTZE [16] relates unfavorable experiences with constriction hyperemia in suppurative disease of the middle ear. Notwithstanding the relief of pain after the application of the elastic band

[16] H. Schwartze: Münch. Med. Wochenschr., May 25, 1909.

to the neck, the work of destruction still goes on, and a sudden chill and fever may reveal the development of thrombophlebitis. The hyperemia treatment is permissible only in the mildest cases, which are free from suspicion of intracranial complications.

In the treatment of otosclerosis he has never witnessed striking benefit from potassium iodide, but in cases of syphilitic labyrinthitis of less than six weeks' duration prompt recovery follows mercurial inunctions. Labyrinthine deafness of longer standing is generally incurable. He has frequently obtained good temporary effects in otosclerosis, especially with simultaneous hyperemia of the labyrinth wall, by systematic sweating by means of hot-air baths. This relieves the congestion in the temporal bone, and the inflammation is favorably influenced. He has never witnessed any harm from the superheated air applied to the patient in bed; the effect on the heart, of course, is watched. Little is to be hoped from mechanical and operative measures in otosclerosis, but there is a broad field for rational internal treatment of the true cause — the dyscrasia — by general treatment, — by general treatment meaning tonic, revulsive, soothing, anti-rheumatic treatment. The frequently accompanying neurasthenia should not be forgotten. Warm saline baths and courses of mineral waters are also useful. Cold water treatment should be avoided. Sea bathing is to be avoided.

THE GENERAL PRACTITIONER AND THE TREATMENT OF THE EARS.

Every year, according to Schwartze,[17] a not inconsiderable number of persons lose their lives in consequence of foreign bodies in the ears, but not so much from the foreign bodies themselves as from the attempts to extricate them. Syringing with warm water is all that should be done to dislodge them. Never, he adds, should the physician allow himself to seek to extract a foreign body with an instrument. An insect in the ear may be killed by cigar smoke or a little warm water, or, better still, by the fumes of chloroform; maggots may be expelled by pouring sterilized oil into the ear; they come to the surface of the oil as they begin to suffocate. The dreaded "earwig" very seldom gets into the ear, but the writer has known many instances of fleas, bedbugs, small beetles and mites entering the ear. Numerous cases have come under his notice in which injury resulted from attempts at extraction of a foreign body when there was none present, or where it was in the other ear. In a case of recent trauma, instruments should be avoided as much as possible. The correct treatment is an aseptic protecting dressing and rest in bed.

TWO CASES OF CHOLESTEATOMA OF THE MIDDLE EAR. RADICAL OPERATION WITHOUT REMOVAL OF THE CHOLESTEATOMA MATRIX (SIEBENMANN'S METHOD).[18]

Siebenmann holds the theory that the matrix of a cholesteatoma is not an invasive or pathologic epithelial growth, but a natural attempt at repair and that the destruction of the bone about these cavities is due solely to increased pressure during periods of retention. He proposes to treat these cases by a free exposure of the middle-ear spaces by the radical operation without disturbing the matrix. The advantages claimed for the method are: Epidermization is complete in three to four weeks; there is less tendency to exuberant granulation and narrowing of the cavity; there is less danger of lessened hearing after operation. A supposed tendency to exfoliation and relapse is not the experience in Siebenmann's clinic. Two cases operated upon by this method are cited from the writer's practice. In the first, a boy of fifteen years, the epidermization was complete in six weeks, and whispered speech was heard at 40 inches, while in the second case, a girl of seventeen years, the epidermization occurred in three weeks, with a whisper hearing of over 9 feet.

THE PATHOGENIC INFLUENCE OF THE EYE ON THE EAR.

Referring to the observation of Rollet, that under the irritation of eye disease, such as disease of the cornea, iris and choroid, the phenomena of tinnitus may be produced, the writer[19] details two cases where this symptom was present. In one with extensive choroidal changes, the tinnitus recurred only when the eyes and head ached. In the other the tinnitus corresponded to the eye chiefly affected.

INFLUENCE OF OTITIS MEDIA ON OLFACTORY PERCEPTION.

Many authorities have noted in abscess of the temporal lobe consequent to otitis media a disturbance of the olfactory sense perception. Urbantschitsch[20] found, in one case, that the olfactory disturbance remained after complete healing of the cerebral abscess, and investigated as to how far aural inflammations alone imply olfactory disturbances. Out of 30 cases of unilateral otitis media, 22 (over two thirds) showed this symptom on the respective side of the nose; in 16 cases the perceptive power was decreased and in 6 cases increased in respect to the other nostril.

TREATMENT OF FACIAL PARALYSIS DUE TO DIVISION OF THE FACIAL NERVE IN THE MASTOID OPERATION.

Marsh[21] reports two cases in which the facial nerve was divided during a mastoid operation. In one case the facial nerve was completely divided, and the proximal end frayed and everted by the gauze packing. The proximal end was teased into its normal position, — coming almost in contact with the distal end; two or three strands of fine chromic gut were placed around the nerve, the ends being inserted into the bony canal and the parts protected for a short time by gutta percha tissue in the manner described by Sydenham.

[17] H. Schwartze: Münch. Med. Wochenschr., June 8, 1909.
[18] E. Hamilton White: Montreal Med. Jour., December, 1909.
[19] G. Sterling Ryerson: Canad. Pract. and Rev., July, 1909.
[20] V. Urbantschitsch: Monatsschr. für Ohrenh., No. 3, 1910.
[21] F. Marsh: Brit. Med. Jour., June 5, 1909.

As no sign of regeneration appeared in a month (Feb. 13), it was decided to reopen the cavity and examine the nerve ends. The ends were readjusted and a strand of fine chromic gut was with difficulty inserted in each of the aqueduct openings. The post-aural wound was closed and the cavity rapidly healed. Gentle galvanism was continued, but it was not until the end of June — four months later — that signs of power commenced in the mouth muscles; the improvement steadily extended to the other muscles, and the power had by May 7 returned to all except the corrugators of the brow.

EINE NEUE BEHANDLUNGSWEISE DES MENIÈRE-SCHEN SYMPTOMEN-KOMPLEXES. (VIBRATION MASSAGE FOR THE MENIÈRE SYNDROME.)

Herzer [22] found vibration massage so effectual in migraine, chronic rhinitis and connected conjunctivitis, and in neuralgia of the cranial nerves, that he applied it in a rebellious case of Menière's disease. The vibration massage was applied to the nasal mucosa, and the active hyperemia in the head induced by reflex action had a favorable influence on the inflammatory process and congestion in the semicircular canals. The case described in detail was that of a man of forty; no benefit had been derived from the usual drug treatment. The massage was applied to the nose every second day at first for twelve days; then three, then two times a week for about ten weeks, and there has been no recurrence during the two years since.

REFLEX AURAL NEUROSES FROM EYE STRAIN.

Of tinnitus due to eye strain, Theobold [23] has observed three distinct varieties, the more usual or vascular type, the relatively low-pitched whirling or fluttering sound caused by irregular contractions of the tensor tympani, and the high-pitched, almost musical, intermittent tinkling produced by contractions of the stapedius muscle. The evidence in favor of the ocular origin of the aural sensations mentioned is in their disappearance after the relief of the eye strain, their greater intensity when the eye strain is most troublesome, or their appearance or aggravation by use of the eyes. The ocular fault most often present is astigmatism. The tinnitus is, in all probability, best explained by a vasomotor disturbance of the intralabyrinthine vessels.

THE OCULAR MANIFESTATIONS ASSOCIATED WITH INTRACRANIAL LESIONS COMPLICATING AURAL DISEASE.[24]

"The eye symptoms of reflex origin are influenced through the eighth or auditory nerve. The simultaneous supply of the ear and the eye by fibers of the trigeminal nerve explains why, in purulent middle-ear disease, there is irradiating, boring pain in the orbital cavity, as well as supra-orbital and infra-orbital neuralgia. Associated with this condition there are often conjunctivitis and lacrimation. Reflex blepharospasms have been observed.

"In brain abscess, ocular symptoms may be absolutely lacking, or they may occur so late as to make it impossible to wait for their appearance. In meningitis ocular symptoms are frequently present, but are variable. In extradural abscess and sinus thrombosis there are no eye symptoms unless the condition is extremely far advanced. Labyrinthitis usually has nystagmus as a constant symptom from the beginning of the inflammation."

A PLASTIC MASTOID OPERATION. A NEW OPERATION FOR ACUTE MASTOIDITIS.[25]

The method described by Hopkins consists in making a meatal opening through the concha and posterior canal wall, the complete closure of the posterior or initial incision, and the cicatrization of the excavated mastoid surface; in other words, the application to acute cases of the plastic methods now used in the radical operations. The advantages claimed for this method are its simplicity, the ease of handling, the better appearance, the rapid healing, combined with perfect safety and the better hearing.

ANESTHESIA OF THE EXTERNAL AURICULAR CANAL AND OF THE TYMPANIC MEMBRANE BY ETHYLIC CHLORIDE. A NEW SPECULUM ALLOWING THE INSTANTANEOUS EVAPORATION OF THE ETHYLIC CHLORIDE.

Koenig [26] has modified the method suggested by Dr. Ed. H. Schild of applying ethylic chloride anesthesia to the membrane tympani and the external auditory canal. For this purpose he has devised an ear speculum furnished with a small tube passing along its whole length and ending with an olive to which a rubber tube is attached so that it may be operated by the mouth of the operator. This tube is so arranged that a jet of chloride may be directed against the membrane. This evaporates immediately, producing an immediate freezing of the drum. There is no need of an assistant. The anesthesia is complete and a paracentesis may be performed in ten seconds.

THE CYTOLOGY OF CHRONIC MIDDLE-EAR DISCHARGES.[27]

The claim has been made by Dr. Milligan [28] in an address before Otological Section of the British Medical Association that by determining the cytology of the middle-ear discharges he could differentiate various types of otitis and fix indications for radical operative interference. A criticism of his paper by one of the writers,[29] called forth a reply from Dr. Milligan [30] defending his views as originally expressed. It was of interest to find in this reply that his claim to have found giant

cells in the "exudate" of cases of tuberculous otitis was based on the examination of material collected by a curette, in other words, tissue definitely not in the exudate. As the writers are unable to agree with Dr. Milligan either on pathological or clinical grounds, they submit the results of examined cases where careful percentage counts of cells present were made.

From the results of these cases the writers believe, therefore, that the cytological examination of chronic middle-ear discharges cannot be regarded as having any value as a means of classifying or selecting cases for any particular form of treatment or in making a prognosis.

RADIOGRAPHY OF THE MASTOID REGION.

After employing radiography for diagnostic purposes in the mastoid region Iglauer[31] publishes brief notes of a number of cases thus examined. His conclusions are stated in substance as follows: The most satisfactory Röntgen pictures can be obtained in profile, the rays centering just below the parietal eminence on one side of the skull and directed through the cranium toward the temporal bone on the opposite side. The internal anatomy of the ear can be thus determined prior to operation, to the great assistance of the surgeon. Osteosclerosis of the mastoid secondary to chronic suppuration can usually be diagnosticated in this way, and it is likely the defects in the limits of the temporal bone will appear in the radiogram. Cases failing to heal after operation should be controlled by skiagraphy, as this may reveal the seat of the trouble. The value of the Röntgen examination in cases of acute mastoiditis remains to be determined.

STEREOSCOPIC MASTOID RADIOGRAMS.

The valuable information which the x-ray examination of the mastoid has yielded, prompted Lange[32] to devise certain improvements in the technic.

In the early report of this work it was stated that its usefulness lay chiefly in the examination of the chronic cases where the bone changes were appreciable. But more recent work has shown that acute cases yield just as satisfactory results. Indeed, it seems probable that in any acute case in which the inflammation in the mastoid has advanced beyond the possibility of spontaneous recovery, that is, in which the bone has softened or broken down, a properly made skiagram will reveal the bone change. Conversely, if the skiagram shows little or no bone change, spontaneous recovery may be considered possible, whereas if appreciable bone change is evident on the x-ray plate an operation is usually inevitable. Thus the skiagram may in doubtful cases be the deciding factor for or against operation.

In order to bring out the anatomic and pathologic relations of the mastoid region more clearly, especially the relation of the lateral sinus to the external auditory canal and mastoid cells, stereoscopic skiagrams should be made.

MASTOID OPERATION, SIMPLE AND RADICAL, UNDER LOCAL ANESTHESIA.

In patients in whom an acute or chronic disease contra-indicated general anesthesia, it was formerly his custom, writes Day,[33] to instruct the anesthetist to give as little of the anesthetic as necessary to control the patient. He noticed that these partially anesthetized patients undergoing the mastoid operation gave no evidence of pain while the bone work is in progress, but would immediately struggle or moan or cry out when the soft parts were being cut or operated upon. The problem of local anesthesia in the mastoid operation, therefore, narrowed itself down to anesthesia of the soft parts, including the periosteum.

After using the local anesthesia in a number of this class of cases, Day found it to possess so many advantages that he was led to apply it to many cases in which there is no contra-indication to general anesthesia. There is a great saving of time, fully ten minutes in acute cases and twenty minutes in radical operations, in the actual performance of the operation, not including the time saved in the anesthesia itself. The economy of time in the execution of the operation itself is owing to freedom from hemorrhage and the fact that the facial ridge in a radical can be much more rapidly worked down upon. Warning is given in twitching of the face much earlier in local than in general anesthesia.

He always has black coffee given the patient just as he goes upon the table.

The technic which Day has followed, with slight modification, is that of Neumann. The solution used is a 1% cocaine solution, with the addition of about a dram of adrenalin solution to the ounce, the quantity used being 1 to 2 dr. For the skin surface an ordinary hypodermic syringe is best, while for the subperiosteal work a heavier one, such as an antitoxin syringe, is used.

It is essential that all preparation of the field of operation be made beforehand, as scrubbing and pressure after the injection has been made are objectionable.

The points of superficial injection are along the line of incision. After this the antitoxin syringe is used to inject under the periosteum, three quarters of an inch behind the auricle and then into the tendon of the sternomastoid muscle. Then an injection is made under the periosteum of the canal, though here it is sometimes impossible to get anesthesia because the fluid escapes from under periosteum at the inner end of the canal. This is especially likely to happen if the periosteum has been raised by the burrowing of pus or cholesteatoma. In about five to ten minutes after the injection the parts should be sufficiently anesthetized to begin.

In all, forty-four mastoidectomies were performed under local anesthesia in thirty-nine individuals; thirty-five for simple mastoiditis, two being double; nine radical operations, including

[33] E. W. Day, Pittsburgh: Laryngoscope, vol. xx, no. 2, February, 1910.

three double radicals. The sinus was explored twice and the cerebellum once. These cases include patients of all ages from five years up, all conditions of life, and many different nationalities.

OTOSCLEROSIS: TREATMENT.

In 1892, while the author [34] was connected with the Massachusetts Charitable Eye and Ear Infirmary, Dr. E. D. Spear demonstrated to him the relation between what was then called otitis media catarrhalis insidiosa — now called otosclerosis — and the nasopharynx, and showed how the otosclerosis could be controlled by applications made to the upper air tract. The applications had the effect of irritating the mucous membrane, and so producing a counter-irritating effect on the ear. Their chief effect, however, was to restore the mucous membrane to a normal condition.

For a counter-irritant the author uses a solution of nitrate of silver from 5 to 10% strength, or a saturated aqueous solution of ammonio-ferric sulphate, taking the precaution not to push the effect to much local reaction. The applications are made through the inferior nasal fossæ to the back and side walls of the nasopharynx. At first the treatment is repeated every day, for three to seven days, and then at gradually lengthening intervals. It is discontinued when the mucosa and ear seem to have ceased improving. Should the exigencies of the case demand it, general constitutional treatment, and local ear treatment, such as inflation, should be instituted in addition to this measure of counter-irritation. The beneficial effects of the treatment are soon apparent in the improvement in the hearing, which improvement generally lasts for a long time.

EXHIBITION OF CASES, ILLUSTRATING THE RESULTS OF THE SO-CALLED HEATH OPERATION.[35]

On general principles it is difficult to accept as a good surgical procedure one that advocates the non-disturbance of necrotic tissues, be it either diseased ossicles or carious bone. This is precisely what the Heath operation does. In other words, the aim is to perform a radical operation, which includes the complete exenteration of the cells comprising the temporal bone, with the exception of the tympanic ring and the fragment of ossicles and membrana tympani which are left undisturbed, as the extent of their necrotic involvement seems to make but little difference in the final result. In the experience of Smith, some of the more extensive necrotic cases have made the very best recoveries, both in the way of entire cessation of discharge and in more or less complete regeneration of the membrana tympani, while the ultimate restoration of hearing power has been carried to almost normal. On the other hand, in some cases of shorter standing, where the necrosis seemed to be limited, he was unable to arrest the otorrhea, nevertheless, the hearing distance was greatly increased. The writer's more recent experience, therefore, teaches him that the Heath operation, for the reasons above mentioned, will largely supplant that of the excision of the ossicles for the cure of an otorrhea.

In another class of cases Smith believes this operation to be of the greatest importance. We all see cases of chronic otorrhea in children involving both ears where the hearing is practically normal. Some of these cases are persistently unyielding to any line of treatment other than operative. The simple mastoid operation does not relieve the discharge, and in performing the radical operation there is great danger of interfering with audition. If such a condition were present in only one ear in a young child, the gravity of one-sided deafness would not be so great, but suppose we should perform a radical operation on both ears of a child for the relief of an otorrhea. There is almost a certainty that the hearing will be greatly interfered with, which condition is likely to grow worse. In this event the child, if young, will in all probability become dumb as well as deaf. Even though the aural disease may endanger the child's life, the responsibility of advising a double radical mastoid operation, in view of possible danger to the hearing power and the consequent loss of speech that may follow, should not be lightly assumed by any surgeon.

In concluding, Smith says that he feels inclined to advise the operation in appropriate cases, from the fact that it does not interfere with the membrana tympani and ossicles, thereby not jeopardizing the power of hearing. It would seem best, as a rule, for this reason, that the operation be performed early, before the disease has caused much destruction of the conducting apparatus. Some other points in its favor are that the danger of injury to the facial nerve is very much reduced; the shock from the surgical procedure is considerably lessened; and the recovery is notably quick, while at the same time it corrects the pathologic process within the danger zone, the antrum.

This procedure, furthermore, not only preserves the hearing present at the time of operation, but in the majority of cases actually improves it to a noticeable degree. Then, again, it is suitable in both the acute and chronic variety of cases, and will probably supplant the operation known as ossiculectomy for the cure of an otorrhea.

A THEORY ON THE FUNCTION OF THE MIDDLE-EAR MUSCLES, RESULTING IN A MODIFICATION OF THE THEORY OF HEARING.[36]

The atmospheric pressure presses on the membrana tympani constantly by way of the external auditory canal; it presses from within on the membrana tympani by way of the Eustachian tube only when the tube is opened. The tube is opened during the act of deglutition by the action of the levator and tensor palati (dilator tubæ). At the same time the soft palate is forced upward, compressing the air in the nasopharynx. This compression plus the existing atmospheric pressure

and the increase in volume by heat and moisture sends the air into the anatomic middle ear, that is, the Eustachian tube, the tympanic cavity, the mastoid antrum and the pneumatic cells of the mastoid. What happens when this bolus of air is forced into the middle ear? The pressure in the middle ear becomes greater than the extratympanic (atmospheric) pressure, hence the head of the malleus is separated from the head of the incus, the liquid in the manometer of Politzer rises; then the tensor tympani muscle slowly contracts, due to the stretch of its tendon, and the head of the malleus again locks with the head of the incus; the fluid of the manometer falls. During this adjustment vibratory pressures (sounds) are poorly transmitted. Meanwhile the air in the middle ear is being absorbed, while the work of the tensor tympani is growing less, due to the lessened intratympanic pressure. The absorption of air in the middle ear causes a continuous variation of pressure. As the intratympanic pressure lessens, the tensor tympani muscle gradually relaxes till the intratympanic pressure equalizes the extratympanic pressure when both tensor tympani and stapedius muscles are at rest. Now the absorption of air continues and the intratympanic pressure becomes less than the extratympanic pressure. The stapedius muscle begins its work to keep the foot plate from being pushed into the vestibular window, and again to establish the equilibrium of the ossicular chain. Soon, due to reflex action, another swallow takes place and the tensor tympani begins its work again while the stapedius muscle rests. At the time of deglutition the stapedius muscle relaxes and the tensor tympani muscle contracts.

What are the advantages of this theory? They are many. It gives a rational physiologic action of muscles. These muscles do not act primarily to keep certain membranes tense or to adapt them to certain sounds, but to equalize constant pressures, and this adaptation to constant pressures brings about an ideal tension of the whole drum ossicular apparatus, causing this apparatus to be in a state of equilibrium, the best possible condition to conduct any and all sounds. What would result if the Eustachian tube remained open? If we had patent tubes we would hear our own voices, as if we talked in a barrel; besides, the tensor tympani and stapedius muscles would soon cease to act, for the tensor tympani would have to be in a state of constant contraction to overcome the slightly increased intratympanic pressure over the extratympanic pressure due to the increased volume by heat and moisture. Without contraction of the tensor there would be no tension and no equilibrium. The muscle would become hypertrophied, and then degenerate, while the fate of the stapedius muscle would be atrophy from no work to do. Muscles must have their periods of rest. Thus the muscles are accomodative to intra- and extra-tympanic pressures and only indirectly subserve sound or vibratory pressures. Physiology teaches that it takes time for a muscle to contract. We know that after swallowing it takes a short time to hear plainly again, and also after a patient's ears are inflated the tensor tympani may be some minutes or hours before it is able to overcome the intratympanic pressure and keep the head of the malleus in locked apposition with the head of the incus. Sounds do not wait. It is difficult to think of muscles accommodating themselves to sounds. We hear immediately. These muscles are too slow to accommodate our middle-ear apparatus to the sounds of an orchestra, but rather they keep the apparatus in an ideal state of equilibrium. While the tensor tympanic muscle was adjusting itself to the bass violin, the piccolo would be lost, according to the old theories. An explosion has no consideration for the intrinsic muscles; it ruptures the drum membrane or wrecks the labyrinth if we are close enough. Even the ciliary muscle of the eye does not act immediately to a strong light; we may watch it contract. The function of the intrinsic muscles is to keep the middle-ear apparatus in equilibrium so that the vibratory pressures may be conveyed to the perilymph. It is ready at all times to receive the simplest to the most complex combinations of sound.

REPORTS OF CASES AND DEMONSTRATION OF SPECIMENS.

By A. L. CHUTE, M.D.

A CASE OF HEMORRHAGE FROM THE PROSTATIC URETHRA.

I SHOULD like to report briefly the case of a man thirty-six years old whose left kidney I removed for tuberculosis nearly two and one-half years ago. Because of a marked tuberculous involvement of the bladder he required after-care for a long time, but for some time he had been perfectly well, passing a clear urine every two or three hours during the day.

On Feb. 4, 1910, he noticed that his stream was suddenly shut off during urination; then that he passed a clot of blood. When I saw him in the afternoon his bladder contained 8 or 10 oz. of very bloody urine, but it could be drawn through a catheter easily. It was the same in the evening when I advised him to enter a hospital.

On the morning of Feb. 5 I pumped out of his bladder a handful of clots and a lot of bloody urine, and sent him into a hospital for observation. During the forenoon I removed a double handful of clots and examined his bladder as well as I could. I could not make out that his bleeding was from his remaining kidney, though the view was not very satisfactory. I tied a large-eyed catheter into his bladder. In the late afternoon I again pumped from his bladder a small basin full of blood and clots. His bleeding was by this time beginning to affect his general condition.

On opening his bladder that evening, and turning out the clots, I was unable after the most careful search to find any cause for his bleeding within his bladder. There

were several little rough places on and near the trigone, probably healed ulcers, but no bleeding points. I could not determine that blood came from either ureter. There was, however, a steady trickle of blood from the urethral outlet of the bladder. Gauze was packed into the outlet and a tube placed in the bladder. There was practically no bleeding after operation, and he has made a good recovery.

The case seems to be one of spontaneous bleeding from the posterior segment of the urethra. I have no knowledge as to its etiology, but suppose that it depends upon a tuberculous ulceration.

TWO PROSTATIC SPECIMENS.

These are two prostates that I removed within a few days of one another, about a month ago. The patient with the large mass had had an acute retention three weeks before and was dependent upon a catheter. The man with the smaller mass had a residual of about 8 oz. His urine was light in gravity and infected; he had been having chills, doubtless due to back pressure upon his kidneys. His prostate was of the small fibrous type, and what I was able to remove weighed but 1¼ dr. Though the younger man by some years, yet his condition was the more serious since he had begun to show secondary renal involvement.

My object in showing this prostate is to protest against the routine use of the term "prostatic hypertrophy" when we really mean "prostatic obstruction." There are enlarged prostates that are not obstructive, and small ones that are. I believe that the seriousness of a prostate *per se* depends almost wholly upon the extent to which the kidneys are embarrassed or involved and that this is not at all in proportion to the size of the prostate. I am convinced that our routine use of the term "hypertrophied prostate," in connection with cases of urinary obstruction, leads those who are less familiar with this condition to overlook cases of serious obstruction, simply because there is no hypertrophy of the gland. I have seen a number of such cases. We could make this less likely to happen if we commonly accentuated in these cases the obstructive element, which is the important one, rather than the hypertrophic element, which is not necessarily important.

URETERAL CALCULUS.

This stone is from the ureter of a young woman, twenty-eight years old, whom Drs. Blake and Gay were good enough to transfer to me at St. Elizabeth's Hospital. She had had attacks of pain in her right kidney region for four years. These attacks would last from one to two weeks at a time, and would be attended with tenderness. She had had negative radiographs. Her urine, which was usually about 1,015, showed a good trace of albumen and contained pus, blood, an occasional cast and calcic oxalate crystals. She had no symptoms referable to her bladder.

I found that several ureter catheters of different sizes and shapes were held up, in her right ureter, at a point 10 cm. from the bladder.

Dr. Percy Brown then took his radiograph after I had passed into the ureter a catheter with a metal stylet. You will see the shadow that Dr. Brown pronounced to be that of a stone just to the outside of where the catheter was stopped. An extraperitoneal exposure of the ureter showed this stone about ¾ in. below the pelvic brim. It was easily removed and the patient made a good recovery.

A CASE OF DIVERTICULUM OF THE BLADDER.

Here is another plate Dr. Brown made for me last week. The patient was a man thirty-four years old, whom I saw with Dr. A. C. Pearce. This man had had several attacks of urethritis and had what was practically a colon bacteruria that Dr. Pearce had treated by vaccines for a considerable time without being able to clear up. On examining his bladder I was able to find and catheterize his right ureter. This showed a normal, uninfected urine. On his left a little above the normal position of the ureter I saw an opening that might have been a dilated ureteric orifice or the opening of a congenital diverticulum. A catheter could be passed into it for an indefinite length, but gave fluid that was the same as the distending medium. The question as to whether this was a dilated ureter or a diverticulum was very definitely settled by Dr. Brown's radiograph, after I had passed a catheter with a stylet. The septum that divides the bladder from the diverticulum is, of course, not shown, but the curve of the catheter gives a good idea of the size of the diverticulum.

END RESULTS IN A CASE OF RENAL CALCULUS.

By DR. E. A. CODMAN.

I want to take this opportunity to put on record the final result of a case which I reported with others (Case xvi) in the BOSTON MEDICAL AND SURGICAL JOURNAL for Aug. 5, 1909. At the time of my first operation, Jan. 23, 1909, this patient presented the problem of a choice between single and double nephrotomy. This x-ray, which was published in the paper referred to, indicated that the stones in the left kidney were far larger than those in the right. Cystoscopy showed that a large amount of pus was pouring from both ureters at infrequent intervals. The indigo-carmine test was delayed so that, after watching for an hour or more, I sent the patient back to the ward without knowing which ureter secreted the pigment first.

The relative sizes of the stones decided me in attempting to remove the left first. To my surprise I found an almost normal-appearing kidney substance, the large stone occupying a dilated thickened pelvis and the smaller one about half in the calyces. Extreme shock prevented any thought of removing the other stones on the right at the same sitting. The patient's condition was very bad for several days, but he soon began to progress favorably. I thought it best to put off a second operation for another year.

He re-entered the hospital in November, 1909, considerably weaker and having suffered several attacks of pain in the meantime. In one of these the symptoms were on the left and there was discomfort on that side much of the time between the attacks. Cystoscopy gave the same result as before and the indigo-carmine was again delayed several hours.

On Nov. 19, 1909, I operated on the right kidney, which I found in very poor condition compared to the left. The stone, though much smaller than the other, was harder to remove and the branches in the calyces apparently were imbedded in the kidney substance. They broke off and had to be removed singly.

The patient bore the operation well, but the wound became badly septic and he died in a uremic and septic state in about ten days. At the autopsy perinephritic sepsis was found on the right, and numerous small abscesses were present in the substance of the kidney. The left kidney from which the large stone had been removed in January presented an interesting condition, showing that the removal of the gigantic stone had actually done more harm than good. The kidney substance was in fair condition, but the pelvis was full of pus and was almost as large and thickened as when it contained the stone. The upper opening of the ureter was minute; evidently the contraction incident to removal of the stone had resulted in stenosis and the over-stretched pelvis had filled with pus. Enough urine had seeped through the minute opening to prevent

suppression, but this necessitated a considerable intrapelvic pressure.

I am convinced the patient would have lived had I known enough to drain the left kidney at the time of my second operation. Possibly a right nephrectomy at the first operation would also have saved him. It certainly would have, could he have stood the shock of a double nephrotomy or right nephrectomy and left nephrotomy.

Dr. Lincoln Davis, Boston, showed

A PROSTATIC SPECIMEN.

I wish to show this specimen of an enlarged prostate on account of its unusual size; as you see, the fragments fill a pint jar; it weighs 275 gm. — about 9 oz. It was removed by the suprapubic route. The operation was somewhat of an emergency on account of severe hematuria. On this account, and as there had been no preliminary study of the case, I chose this route, although as a rule I greatly prefer the perineal. I should think that a prostate of this size would offer great difficulties in removal through the perineum.

The operation was performed Jan. 14, 1910; the patient has made a complete recovery. He had led a catheter life for fourteen years previously.

Dr. R. F. O'Neil showed

A PROSTATIC SPECIMEN.

I wish to show this post-mortem specimen from a patient who died about four months after a prostatectomy. You will notice the bladder is very large and the kidneys are in an advanced pyelonephrotic state, the right one being occluded. Clinically there were several features in this case which made it one of interest and difficult to deal with.

The patient was a man of sixty-four with urinary symptoms extending over a number of years; the urinary frequency became so marked that he was unable to continue his occupation, that of a letter carrier.

Examination showed an active, rather spare man, apparently in fair condition. The reflexes were normal. He presented an abdominal tumor in the median line, extending above the umbilicus. By rectum the prostate was moderately enlarged. By catheter I drew off 16 oz. of clear urine, which flattened out the tumor somewhat. The urine was clear, acid, specific gravity 1,005, albumen slight trace. I then put him on constant drainage, not caring to empty the bladder at once. I had a clamp on the catheter and had at first 6, then 10 oz. an hour drawn off. The bladder seemed to contract down fairly well. On one occasion the clamp slipped and the bladder became empty, causing intense vesical spasm and hematuria. This was relieved by morphia and replacing 16 oz. of salt solution in the bladder. After a couple of days the bladder remained empty. I never knew the capacity of the bladder, but it was enormous.

A cystoscopy showed a large intravesical growth, both laterals and a median lobe. In order to further rest the muscularis of the bladder and explore digitally the bladder, I did a suprapubic cystotomy under cocaine. This was followed in a few days by a suprapubic prostatectomy. He did well for ten days and was up. He then began to vomit and hiccough and became very ill. He remained in a desperate condition for a couple of weeks, but finally recovered and left the hospital. He was on constant drainage while he was so very ill. The urine was turbid and the specific gravity about 1,008. At the time of his leaving he had a residual of 12 oz. at the end of twenty-four hours. I understand this amount increased after he got home, and until the time of his death, from renal insufficiency, about four months after his operation, he used a catheter once a day.

The points of interest in this case are the enormous over-distention of the bladder, of which the patient was ignorant, and the fact that a man can go as long as he did and through a severe illness with so very little renal tissue.

I believe the outlook, where there is much bladder distention, is poor. In this case the organ was unable to take up its work entirely.

Demonstration of Patients.

Dr. G. P. Sanborn showed

A CASE OF TUBERCULOSIS OF THE TESTICLE.

The case shown is one of tuberculous cystitis extending over from five to ten years. Five years ago, Dr. J. H. Cunningham made the diagnosis by cystoscopic examination. Four years after this, the patient developed a swollen testicle which I later proved to be tuberculous. I have given tuberculin for about eighteen months. The testicle is now approximately normal in size, the epididymis hard and somewhat enlarged. Symptoms of cystitis have disappeared.

Demonstration of Instruments.

STEREO-CYSTOSCOPE.

Dr. H. W. Beal, Worcester: I wish to show one of Jacobi's stereo-cystoscopes. I have not had a chance to use it. It has an adjustable eye-piece, two objectives and two series of lenses with an irrigating attachment.

Dr. Geo. P. Sanborn read a paper by invitation entitled

THE PLACE OF TUBERCULIN IN THE IMMUNIZATION OF URO-GENITAL TUBERCULOSIS.[1]

Dr. Hugh Cabot read a paper entitled

THE VALUE OF TUBERCULIN IN TUBERCULOSIS OF THE URINARY TRACT.[2]

Dr. H. H. Hartwell read a paper entitled

BACTERIAL VACCINES IN BIOGENIC INFECTIONS OF THE URINARY TRACT.[3]

DISCUSSION.

Dr. Cleaveland Floyd, Boston: In regard to tuberculosis of the kidney, it should not be forgotten that this organ is in some degree at least a filter, and the excretions of the tubercle bacillus may be intermittent. On this account frequent animal inoculation may be necessary in order to detect an existing tubercular lesion. It must be remembered that tuberculosis in one part of the genito-urinary tract may be associated with the same disease in other parts which give no symptoms. Recently a case of epididymitis was given a tuberculin test to determine whether the lesion was tubercular or not. No other part of the genito-urinary tract was thought to be diseased. A typical tuberculin reaction was obtained, followed by pain referred to the right kidney, and albumen and pus in the urine. Animal inoculation gave positive tubercular lesions. The use of tuberculin still has a definite place in diagnosis in spite of the use of the cystoscope. When a correct diagnosis is so important as in tuberculosis of the kidney, the subcutaneous tuberculin test should be used in preference to other tuberculin tests, which are often misleading. Furthermore, only the subcutaneous test gives local symptoms which are all important in locating the lesion. In the early cases of genito-urinary tuberculosis it remains to be proven whether we can get along without operation, relying upon tuberculin. It would seem best for the present that the patient should first have the benefit of an operation, and if that is refused,

[1] Journal, p. 455.
[2] Journal, p. 471.
[3] Journal, p. 472.

then fall back upon tuberculin. In this connection the following case is of interest. A woman of thirty was found to have tuberculosis of the right kidney, as shown by cytoscopic examination, the presence of tubercle bacilli in the urine and positive animal experiments. The symptoms of painful and frequent micturition were very troublesome. Operation was refused and she has been under tuberculin treatment for some ten months. During this time the urine has cleared up, all symptoms have disappeared and her general condition is excellent. She is now pregnant and a second cystoscopic examination has been deferred on that account. I agree with Dr. Cabot that tuberculin may have a large field in preventing the recurrence of foci of tuberculosis, or at least of preventing the lighting up of those that remain behind following operation. Tuberculosis of the kidney generally being a hematogeneous infection denotes, when it is present, the entrance of the tubercle bacilli into the circulation from some source, and the second kidney as a filter is, therefore, always exposed to infection in such instances. The use of tuberculin may materially lessen this danger by increasing the general resistance and controlling the primary infection. In advanced cases of genito-urinary tuberculosis, troublesome symptoms may be controlled and considerable comfort be maintained with small frequently repeated injections of tuberculin. When there is a pyogenic infection superimposed upon a tubercular process, tuberculin should be used systematically first, and later other bacterial vaccines added as required.

DR. A. L. CHUTE: My personal use of tuberculin in urinary tuberculosis has been limited. In 1905 I brought some tuberculin from Europe and used it in a few cases, some of which I recall. This was the old tuberculin and the doses were much larger than those used now. I began with 1-400 mgm. and increased to ½ mgm.

One patient, with what was clinically urinary tuberculosis, but what was never definitely demonstrated to be tuberculosis, improved very much. He became practically well, having no symptoms and a clear urine. Some two years later this man died of another cause, and at autopsy no signs of tuberculosis were found, though they were especially looked for because of his previous trouble. I saw this man but once and had no opportunity to re-examine him after the disappearance of his symptoms, but I do not believe that he had tuberculosis.

In another case there was no apparent result, and after a time this man disappeared without any improvement in his symptoms.

Two years ago, at my suggestion, a patient with tuberculosis of his prostate, and probably kidneys, was given a very long treatment with the smaller doses of tuberculin that are now used. At times this man felt that he was better, but the disease made steady progress and he has recently died.

It is my feeling that few of the results reported from the use of tuberculin are absolutely definite or convincing. In many cases the examination both before and after treatment leaves much to be desired. We require greater accuracy of observation in order to be able to draw definite conclusions.

Some instances have been reported in which tuberculin has been used with good result in cases where, after nephrectomy, tubercle bacilli have been found in the urine. Such cases mean little unless the bacilli have been demonstrated by ureter catheter to be coming from the ureter of the remaining kidney. Otherwise the bacilli may have come from the stump of a thickened tuberculous ureter, or from a tuberculous involvement of the bladder. Both these conditions, in my experience, get well of themselves after the removal of the diseased kidney, though the process of cure may be slow. From the cases of demonstrated renal tuberculosis that simply show improvement under the use of tuberculin, I feel that we can draw no definite conclusions as to its value. I have watched several unoperated patients with renal tuberculosis over a number of years. In them there has been almost without exception times when they have had marked relief from their symptoms. The apparent improvement under the use of tuberculin may simply be one of these fluctuations that occur in the course of the disease.

Finally, in the cases of known renal tuberculosis in which with no other treatment than tuberculin, the tubercle bacilli have disappeared from the urine, it does not necessarily follow that the process has been arrested or cured. Unless we demonstrate by catheterization of the ureters that both kidneys are functioning and secreting non-tuberculous urine, I believe it is much more probable that the diseased kidney has become a small fibrous mass, or that the ureter has become thickened to the point where the kidney is entirely shut off from the bladder. We have had at least two such cases reported before the Society within the past two years. I am convinced that in some instances results that are attributed to the use of tuberculin are the same as those that occur without its use; that in order to really test the value of tuberculin we must have a large number of accurate observations made both before and after its use.

I do not believe that to-day we are justified in advising the use of tuberculin in cases of unilateral renal tuberculosis. In these cases the efficacy of nephrectomy has been proven over and over again. To postpone nephrectomy for any considerable time in a unilateral case, as would be necessary to give the tuberculin treatment a fair trial, would mean running a chance of the second kidney becoming infected by means of the tuberculous process from the diseased side crossing the trigone, causing a stenosis about the well ureter and then ascending that ureter. Rovsing has, I believe, clearly demonstrated the possibility of this. I have seen one specimen and one clinical case in which this seemed to have happened. It seems to me that at present we are chiefly justified in advising the use of tuberculin in bilateral cases, which are for the most part unsuited for any surgical intervention.

Dr. Floyd has raised what I believe to be an important point: that it is not enough to find tubercle bacilli in the urine to make a diagnosis of renal tuberculosis — we must find pus as well. The kidneys are filters, and there is a definite probability that tubercle bacilli originating in other foci may at times pass through them in sufficient numbers to give a positive test in guinea pigs without there being any involvement of the kidney itself.

I trust that in tuberculin we have a remedy that will justify the hopes we have put in it. I believe that as yet little has been actually demonstrated as regards its efficiency; that we should limit its use to double renal infections or to post-operative cases; that it should not be used until a most careful examination of the patient has been made in order that we may know just the extent of the disease, and, therefore, have definite data by which to determine just what has been accomplished.

Dr. Hartwell's conclusions regarding the efficacy of vaccines in the treatment of infections of the urinary tract with the common pyogenic bacteria quite agree with my own observations on this subject. The course in these pyogenic infections is wholly different from that in the tuberculous infections, and cure, I believe, depends about wholly on efficient drainage. The acute cases in which both the kidney pelvis and bladder drain perfectly get well under the use of vaccines, but they

also get well under the use of internal medication alone or with the addition of a little local treatment. When these cases become chronic, and resist the usual method of treatment, it will be found that in a very large proportion of them there is faulty drainage. In cases of this sort I have found the use of vaccines wholly without result. In not a single case that I have found difficult to treat has the vaccine treatment shown any effect. These cases have comprised infections with the colon, staphylococcus, pyocyaneus, proteus and some of the urea-splitting organisms.

It is my belief that the favorable results come from the use of vaccines in the acute and largely self-limited cases, and that these results occur largely in the hands of men who do not appreciate that many of these cases get well under most simple treatment. In this type of infection also it is most important that an accurate examination precede the treatment by means of vaccines. Not long ago I saw a man with a thoroughly disorganized kidney, who had submitted to months of vaccine treatment. It is needless to say that there had been no result, and that his treatment would not have been undertaken, even by the most enthusiastic, had his local condition been known. I am convinced that only such pyogenic urinary infections recover under the use of vaccines as would get well under simple means; that the specific action of vaccines in this class of infections is practically nil.

Dr. R. F. O'Neil: In regard to the use of vaccines in the chronic colon infections, in my experience they have been unavailing. They do not prevent the exacerbations so often seen in this condition, nor do they clear the urine of bacteria.

The sudden remissions of temperature and relief of symptoms referred to their action are seen just as often in cases when vaccines are not employed, and may be put down to the re-establishment of the temporarily shut-off drainage. I have had occasion to look up the literature of late and find that the most favorable results have been reported in the acute and subacute cases which, as has been stated, tend towards recovery under other methods of treatment when there is no obstruction or abnormalitity present.

Dr. C. M. Whitney: In reference to the vaccine treatment, I am entirely in accord with the conclusions expressed here in regard to the drainage. In these cases of bacteriuria which have been due to a secondary cause, either a prostate or a stricture, it has been my custom after removing the cause, if they did not yield to the oxy-cyanide of mercury aided by the improvement in drainage, to have them receive the vaccine treatment.

I am sorry to say that some of these cases have been treated with vaccines for from six to eight months, with absolute failure. One of these has been shown by Dr. Chute to-night, the anatomical lesions for failure being plain.

Dr. S. P. Sanborn: The giving of tuberculin in cases of genito-urinary tuberculosis requires careful attention to the matter of dosage. This applies particularly to the cases having ureteral involvement in which it is conceivable that swelling of the mucous membrane, associated with the focal reaction resulting from excessive dose, might result in occlusion of the duct, accumulation of pus and immediate surgical indication. We must recognize the association of the focal and general reaction produced by large dosage of tuberculin with a lowered phagocytic resistance. We, therefore, have reason for using such initial dose and increments to dosage as shall guard against any prolonged reduction in the phagocytic power of the blood. We can achieve this by starting with a dose small enough not to produce any clinical symptoms, and follow it by weekly dosage, increasing in such a manner that no symptoms are at any time produced. At the end of six months' treatment dosage may have increased from 1-20,000 to 1-5,000 mgm. The giving of tuberculin by the so-called clinical method takes as its guide the production of symptoms of intolerance. When general reaction is produced, the dosage is made smaller. In every case, therefore, general reaction is necessarily produced at times. The maximum dosage finally arrived at is considerably larger in the same period than that reached by the use of the opsonic method. The improvement of the patient appears in some cases to be more rapid. Such a method, however, cannot be devoid of danger. Wright's method, which endeavors to avoid constitutional reaction, is much more conservative and safe, and if the same dosage is finally reached, that is, attained by the clinical method, it would seem that quite as satisfactory degree of immunity should be obtained.

In order that the dosage of tuberculin as given by different workers may be readily compared, it should be based upon the amount of bacillary substance used in each case. The bacillus emulsion, as sent out by certain manufacturers, contains 5 mgm. of bacillary substance for each cubic centimeter of the original fluid, while that of others is said to contain 1 mgm. for each cubic centimeter. Hence 1 mgm. of the original fluid would in the former case contain five times the amount of tuberculin substance that the latter would contain. To secure uniformity, it would seem desirable in all cases to designate the dose of actual bacillary substance given.

Dr. Hugh Cabot: I want to make my position clear about tuberculin. It is still under discussion, but I have seen so many cases in which the improvement was so prompt that I cannot help thinking it was due to the tuberculin and not to an act of God, as Dr. Chute thinks.

Book Reviews.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. de Schweinitz, A.M., M.D. Sixth edition, thoroughly revised. W. B. Saunders Company. 1910.

The sixth edition of this standard textbook has been revised and much new material added. It has now 945 pages, but is not an unwieldy volume. Paper and print are excellent and the illustrations, in number and execution, leave little to be desired. The book is completely up to date. Vaccine and serum therapy and the importance of tuberculin in eye diseases have received attention. The chapter on movements of the eyeball and their anomalies is a very clear exposition of this complicated subject. Sweet's method of localizing foreign bodies in the globe by the Roentgen rays is given in the appendix.

Aids to Microscopic Diagnosis (Bacterial and Parasitic Diseases). By Ernest Blake Knox, B.A., M D. (Dubl. Univ.). New York: William Wood & Co. 1910.

This small book of 156 pages epitomizes in condensed form the more important microscopic methods of diagnosis. It should be of special use not only on account of the subject-matter, but also because of its convenient size.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 29, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL CARE OF DEEP-SEA FISHERMEN.

THERE is no dangerous trade which exacts a greater toll of human life than that of the deep-sea fisherman. At the memorial service held in Gloucester each year the names are read of from fifty to sixty fishermen who have perished at sea. About six thousand men are engaged in deep-sea fishing "out of Gloucester," and so in ten years the loss is one in ten — an appalling rate, but one apparently inseparable from this hazardous calling. The courage of men who are willing to accept such odds as these is not without its recognition, for the well-drawn pictures of their life which James B. Connolly, and Kipling, in "Captains Courageous," have given us have drawn attention to them, and there is a widespread admiration for the type of men who show in such remarkable degree the fine virtue of "everyday heroism." Interest in any movement for their welfare is, therefore, assured.

In a recent report to the Surgeon-General of the United States Public Health and Marine-Hospital Service, Dr. L. L. Williams, surgeon in command of the United States Marine Hospital at Chelsea, has shown that the deep-sea fisherman faces dangers at sea only slightly less formidable than those of the stray dory, the winter gale or the speeding transatlantic liner which brings swift death to many in the fogs of the Banks. The work of the deep-sea fisherman is carried on in small vessels far from shore, and days and even weeks must elapse before medical or surgical help can be secured for men seized suddenly with dangerous illness or injured in their work. This is the only country, as Dr. Williams has pointed out in his report, which has not made an effort to provide medical and surgical care at sea for its deep-sea fishermen. In the North Sea, where there are about ten thousand British fishermen, whose work is done under much less dangerous conditions than those met by the American "Banker," the Royal National Mission to the Deep-Sea Fishermen has provided three hospital ships and four dispensary ships which follow the fleets and render an enormous amount of relief which otherwise would be unobtainable. Dr. Grenfell's work among the fishermen of northern Newfoundland and the poor "liveyere" of Labrador has awakened the greatest interest in this country. The French send a fully equipped hospital ship across the Atlantic each year to the fishing grounds in the vicinity of the islands of Saint Pierre and Miquelon. Through the summer this vessel is constantly on the Banks, giving medical and surgical aid to all who need it without regard to nationality. During the last twelve years, more than five thousand men have received treatment aboard this ship, and in nearly every case it would have been impossible, but for the humanity of those who have provided the vessel, for any medical care to have been received for a number of days. Infected wounds of the hands are particularly common among fishermen and, according to Dr. Williams's report, the most disastrous results have been seen in the wards of the Marine Hospital from failure to secure treatment earlier. Fractures and frost bites are often met with and, in spite of the hardiness of the men, many cases of the acute illnesses which would be expected ashore.

For many years this government has assumed the responsibility for the medical care ashore of American merchant seamen, including deep-sea fishermen, and it would be but a simple and a very natural extension of such relief to provide a hospital ship to carry the benefits of medical and surgical relief to the place where they are so urgently needed. It is this that Dr. Williams has recommended, and all that is needed is for Congress to provide funds to build or buy a suitable vessel and to provide for the cost of its maintenance. It is believed that a schooner following closely the lines of the best type of fishing vessel, provided with ample auxiliary power, would be the most suitable kind of vessel to meet the rather unusual requirements of this work. The cost of such a vessel would probably not exceed $25,000, and the annual expense of maintenance would not be more than $10,000 or $12,000. This would be a very small expenditure for the relief of suffering and the saving of life which would result.

In the recent growth of interest in the con-

servation of our national resources, the conservation of human life has come to have an important part. We have, in the deep-sea fishermen of the North Atlantic, a group in which the apparently inevitable loss of life is very great. If for no other reason than admiration of those who, in their humble daily tasks, face the dangers of the soldier in time of war, any movement to prevent further and needless loss of life should appeal powerfully to all who are concerned with the welfare of their fellow-men. The great need for a hospital ship and the entire feasibility of the plan suggested are vouched for by those who are in the best position to know the facts. It requires only an expression of public opinion to secure it and to carry, under the American flag, the resources of modern medicine to the distant Banks where the deep-sea fishermen of Gloucester and Boston are gathering the harvest of the sea at the expense of far too many valuable lives.

MODERN METHODS IN CLINICAL PSYCHIATRY.

The medical profession in general has only the vaguest conception of the high order of clinical and pathological work that nowadays is being done by its members in many hospitals for the insane. This is nowhere better exemplified than in the report of Dr. Kirby, the "director of psychiatry" (a recently made position) of the Manhattan State Hospital. It appears with much heterogeneous matter in the last annual report of that institution, and should have wider recognition than is possible in a publication of that nature.

In his analysis of 1,152 new admissions it is especially pleasing to note the progressive tendency toward intelligent study of the case as a whole, toward placing more and more emphasis upon both the disturbing causes directly responsible for the initial outbreak and upon the natural make-up and normal tendencies of the individual, thereby obtaining an insight into the real nature of the condition which could never be attained by the closest study and observation of the clinical symptoms alone. Following upon the general adoption of Kraepelin's classification, many cases were, with surprising ease and nonchalance on the part of the diagnostician, at once labelled dementia precox because of catatonic symptoms, conduct disorders and the like which are now being given more serious study, especially as to the evolution and general setting of the symptoms, and are classified more intelligently. As a result there has been a progressive shrinkage in the adoption of the unqualified diagnosis of dementia precox as appears in the following table:

	1904. Per cent.	1905. Per cent.	1906. Per cent.	1907. Per cent.	1908. Per cent.	1909. Per cent.
Women,	31.8	28.6	23.3	20.7	15.3	12.9
Men,	—	—	24.7	17.4	18.1	17.5

That is to say, in 1906 24% of new admissions were diagnosed dementia precox, whereas in 1909 15.2% were definitely classified as such. While awaiting developments of diagnostic importance, 4.3% of admissions were classed as "allied to dementia precox," with 65% of recoveries. These for the most part were made up of patients who, because of negativistic or catatonic tendencies, were inaccessible to satisfactory examination or about whom nothing was known relating to the development of the signs and symptoms of mental aberration. In support of this temporary grouping is the fact that in certain instances definite manifestations occurred later on during the disease which denoted that the case properly belonged in the manic-depressive group.

3.4% of cases were appropriately classified under the heading of "paranoic conditions." In such patients the mental symptoms developed at about the fortieth year of life and were characterized both by systematized and dementia precox-like delusions, having in most cases a fairly definite factor, in the shape of some special troublesome experience, for the instigation of suspicious ideas, faulty reasoning power and errors in judgment, eventually leading to delusion-formation. Because of the frequency with which such cases are met, a special classification seems expedient. Althought they develop later than does dementia precox of the paranoid form, and deteriorate slowly or not at all, they nevertheless do not progress to a definite, expansive system of delusions as in true paranoia.

Fourteen cases (or 1.3%) were classed as "depressive hallucinosis," the clinical picture of which is acute depression, prominent hallucinations (especially auditory) with clear sensorium. Thirty-eight cases (3.5%) of admissions were placed in the group of "depressions undifferentiated," inasmuch as certain features were lacking which would allow their identification with any of the better known forms. This practice of withholding a definite diagnosis in certain cases which do not conform to a special clinical type, meanwhile giving such case a term somewhat descriptive, for example, "depressive hallucinosis," "allied to dementia precox," etc., should lead eventually to a more perfect classification of mental diseases.

In the report of the pathologist, Dr. Rusk, a noticeable feature is the striking predominance of bronchopneumonia as the terminal infection in general paralysis. It is not recognized clinically in most instances because of the difficulty experienced in making a thorough physical examination in the end-stage. Of thirty cases autopsied, as many as 93.3% showed fatal lung involvement. In the 1906 report of the Massachusetts State Board of Insanity only 14% of paretics in our state hospitals were said to have died from this complication and other pulmonary lesions. A comparison of the two percentages tends to substantiate the claim of general difficulty and error in determining clinically the exact cause of death in such cases.

In addition to the daily staff meeting, a weekly conference is held at the Manhattan State Hospital for review of all cases coming to autopsy, at which time anatomical material of interest is displayed. This must be of great value to the clinical staff and, as it tends to associate more closely the clinical and pathological departments, might advantageously become a custom in all institutions for the insane.

THE DUSTLESS AGE.

IN hygiene of the schoolroom no subject has been given more attention than the prevention of dust. The dustless eraser, the dustless floor dressing and dustless heating and ventilation have accomplished much. Dustless streets, not only for the preservation of health, but of the streets themselves, are now the only streets tolerated where good roads are known. In the home the dustless cleaner reigns, and the broom, historic emblem of general cleaning, lives as a memory of the time when witches rode in air and housecleaning meant the vigorous awakening and thorough dissemination of every possible carrier of every troublesome germ. Cold air enters the house heater through a muslin screen. Ashes from the kitchen range go directly by metal pipe to metal container in cellar below. Smooth floors with rugs easily kept clean have banished the tacked-down carpet of our forebears. Verily this is progress. No more the stuffy, heavily draped room. The day of fresh, clean air has come. In prevention of dust through smoke we are yet, however, sadly negligent. In spite of efforts to prevent dust and to be well rid of it we pollute all outdoors, that is, city outdoors, with tons of it in clouds of slowly rising and as inevitably settling smoke. From our office window we see dozens of belching chimneys. Within upon our writing table are countless black particles of no uncertain origin. We visit other cities and are glad that ours is no worse, but this grain of Pharisaical short-lived content makes our own no better. We are inclined to think of two efficient remedies, — the enforcement of existing law and the creation of any new law needed. Then, as a result, will come public awakening and public indignation, and naturally in this, as in all matters of preservation of health and comfort, the medical profession must lead.

MEDICAL NOTES.

SUICIDE IN RUSSIA. — Returns indicate that upwards of 625 attempts at suicide were made in Russia during the month from Aug. 14 to Sept. 13. Over 300 attempts were successful, and between one half and one third of this number were persons living in small towns.

CAUSES OF DEATH. — According to the most recent Census Bureau's mortality report, influenza was held responsible in 1909 for one third less deaths than in 1908. A striking feature of the report is the definite increase of deaths due to pneumonia, nearly 9,000 more in an area covered by about half the United States than in 1908, being an increase of more than 9 to each 100,000 persons. The total number of deaths from pneumonia was only seven less than those from tuberculosis. Certain children's diseases showed an improvement, but there was an increased number of deaths in 1909 from diseases of the circulatory, genito-urinary and nervous systems.

RECENT DEATHS ABROAD. — There have recently been a number of deaths of prominent continental physicians. Prof. Eduard Henoch, distinguished for his work on diseases of children, died Aug. 26 at the age of ninety. He was born in 1820 in Berlin and studied there under Romberg and Schönlein. He later served as an assistant to Romberg, and in 1858 was appointed extraordinary professor at Berlin, where he had the unique distinction of passing his entire career. For twenty-one years he was the head of the clinic for children's diseases in the Charité. He had not practised since 1894.

Prof. Friedreich D. von Recklinghausen, distinguished as a pathologist, has also recently died. He was born in 1833, was a pupil of Virchow and was later his assistant. He was appointed professor of pathological anatomy at the Univer-

sity of Königsberg in 1865, later went to Würzburg, and in 1872 became professor at the University of Strassburg, a position which he resigned in 1906.

The Cost of Progress. — In humanitarian circles it is customary to speak of civilization as a disease, and to compare the noble savage and the effete citizen in a manner greatly to the latter's disadvantage from the point of view of health and constitution. Facts do not lend unqualified support to this kind of idealism, yet it must be confessed that the list of industrial diseases, already formidable, is a constantly growing one, and that every new invention carries attendant evils in its train. Among distinctively modern diseases may be instanced the poisoning produced by the fumes of calcium carbide or acetylene; the headache, dyspepsia, cardiac failure and sensory disturbances traceable to the manufacture and use of aniline dyes; the frothing of the blood, known as caisson disease, which follows too rapid decompression in workers at the foundations of bridges; the functional neurosis known as telegraphists' cramp, resulting from the use of the Morse key; and the numerous affections of the skin, lungs, digestive tract and eyes due to irritation by organic or inorganic dusts of industrial origin. Among the last-named, special mention may be made of "shoddy fever," caused by the dust arising from pulverization of wool-containing rags. A modern danger *par excellence* is that of electrocution by contact with live wires, to which innumerable workers are daily and hourly exposed. Direct currents of 700 volts pressure and upwards, and alternating currents of half that amount, are officially recognized as dangerous to life, but even lower charges have produced fatal results. With the sad cases of Dr. Hall-Edwards and Dr. Kassabian fresh in their minds, medical readers do not need reminding of the terrible potentialities of the Roentgen ray. The conquest of the air is proving so costly to life that there is a growing feeling that its commercial exploitation by health and pleasure resorts in the form of "flying weeks" has been altogether premature, and should for the present be stopped. If, therefore, we cannot admit that civilization is itself in essence pathological, neither can we deny the costliness of its benefits or the pathogenetic associations of its every forward step.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Sept. 27, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 11, typhoid fever 26, measles 4, smallpox 0, tuberculosis 43.

The death-rate of the reported deaths for the week ending Sept. 27, 1910, was 17.42.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Sept. 24, 1910, was 227, against 205 the corresponding week of last year, showing an increase of 22 deaths, and making the death-rate for the week, 17.65. Of this number 125 were males and 102 were females; 220 were white and 7 colored; 143 were born in the United States, 78 in foreign countries and 6 unknown; 48 were of American parentage, 148 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 40 cases and 4 deaths; scarlatina, 11 cases and 0 deaths; typhoid fever, 22 cases and 2 deaths; measles, 6 cases and 0 deaths; tuberculosis, 47 cases and 19 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 18, whooping cough 1, heart disease 21, bronchitis 2. There were 18 deaths from violent causes. The number of children who died under one year was 68; the number under five years, 101. The number of persons who died over sixty years of age was 66. The deaths in public institutions were 86. Cerebrospinal meningitis, 2 cases.

Of the above infectious diseases the following were non-residents: Consumption, 4 cases and 2 deaths. Scarlet fever, 1 case. Typhoid fever, 1 death.

Deducting deaths of non-residents, the total is 199 and the death-rate is then 15.47.

New Hampshire Surgical Club. —The New Hampshire Surgical Club will hold its fifteenth annual meeting at Hanover, N. H. Among the papers to be presented is one by Dr. Harvey Cushing on "Brain Tumors and their Surgical Treatment." In the course of the meeting a surgical clinic will be held in the Mary Hitchcock Hospital.

Deaths from Drowning in Maine. — It is stated that during the past summer sixty-one persons, nearly all of them residents of Maine, have been drowned in that state. Nineteen were drowned in June, twenty-four in July and eighteen in August, most of them due to accidents in canoes or other boats, or while bathing.

"Hospital Day" in Lynn. — Money was raised for the Lynn Hospital on Sept. 24 and

25, as has been the custom for some years past. Collections in the churches and money given by individuals, and through the sale of various objects, it is expected will amount to $25,000.

NEW DEAN OF DARTMOUTH MEDICAL SCHOOL.— Dr. John M. Gile, Professor of the Science and Practice of Medicine at the Dartmouth Medical School has been appointed Dean of the Medical Faculty to fill the vacancy caused by the death of the late Dr. William T. Smith. Dr. Gile is forty-six years old and was graduated from Dartmouth College in 1887 and from its medical school in 1891. He has for many years been instructor in the department of medicine and was appointed professor of medicine in 1896. He is surgeon to the Mary Hitchcock Memorial Hospital.

NEW YORK.

BEQUESTS. — By the will of the late John E. Schoenberg, of New York, $60,000 is left to charitable and benevolent objects. It is stated that the larger part of the amount goes to the National Jewish Hospital in Denver, in the management of which the deceased was personally interested, and that the remainder is distributed among New York and Cleveland charities. Among other charitable bequests in the will of the late Miss Elizabeth Dunleary, of New York, are $1,000 each to St. Vincent's Hospital and the Home for the Aged of the Little Sisters of the Poor.

TRACHOMA. — On the Greek steamship *Athenai* which arrived from Europe on Sept. 21 the examining physicians of the United States Marine-Hospital Corps were surprised to find eight cases of trachoma. Five of these were so well developed that it was considered impossible that a medical examination of the passengers upon embarkation should not have detected them, and this caused the officials to make an inquiry. They found that it was believed on the vessel that it was sometimes the practice of aliens suffering with diseases to hire substitutes to take the necessary medical examination for them. The place where these examinations are made is some distance from the places of embarkation, and it is possible for a person to get a substitute to pass the examination in his name, and then, having his card stamped "O. K.," with this in his possession to walk on board and trust to luck to get past the examiners on this side. As the steamship companies are liable to a fine of $100 for every such affected passenger brought to port, it is probable that prompt measures will be taken to put an end to this practice, should it be proved to have been resorted to.

STRAUSS MILK DEPOTS. — A letter containing a copy of a set of resolutions passed at a recent meeting of social and philanthropic workers, held at the Colony Club at the call of Mrs. J. Borden Harriman, has been sent to Nathan Strauss, in which the decision of Mr. Strauss to close the infants' milk depots is deplored and he is urged to continue the work. In the letter warm appreciation is expressed of his "long and sustained efforts to bring about the pasteurization of city milk supplies and to reduce infant mortality thereby." It was resolved at the meeting that a committee should obtain a conference with Mr. Strauss and endeavor to dissuade him from his present purpose, and among the members of this committee are Dr. Abraham Jacobi; Robert W. De Forest, of the Charity Organization Society; Homer Folks, of the State Charities Aid Society, and R. Fulton Cutting, of the New York Association for Improving the Condition of the Poor. In the meanwhile, the following notice has been posted at the various Strauss stations: "On Oct. 1 this infant milk station will be closed, and the sale of the baby milk stopped, on account of the misrepresentation and the vicious attacks of the New York *Herald* and Paris *Herald* on Mr. Nathan Strauss and his milk pasteurization work."

1. The various precipitation tests for the diagnosis of syphilis are too unreliable to be of much practical value. The Schurmann color reaction has been extensively tried and found to be worthless. The favorable results claimed for the interdermic reaction are encouraging, as the test is very simple. Will's cobra venom test has excellent claims, but is too complicated for ordinary use. That the Wassermann reaction as originally performed is not entirely satisfactory is shown by the many attempts that are made to improve and simplify it. That of Noguchi in America is most widely employed. The use of urine in place of serum for the Wassermann reaction is not to be recommended. No simple modification has as yet entirely replaced the original Wassermann. The use of barium sulphate suggested by Wechselmann to remove the disturbing complementoid from the patient's serum has apparently given a greater proportion of positive reactions than those obtained by the original method. The non-syphilitic diseases giving a positive reaction include leprosy, frambesia, sleeping sickness, scarlatina, malaria and lupus erythematosus acutus.

3. Freeman, in a very sane article, shows how the wave of sanitary improvement which is accomplishing so much in cities has not yet spread to the country districts. In few states is there adequate supervision of rural communities. Infectious diseases are not reportable. Disease started here spreads rapidly to larger communities. Many cases of typhoid and other diseases that appear in cities after vacation time can be traced to bad sanitation in the country. The farm is the unit of evil with its dangerously situated and ill-cared-for privies and water supplies. There is a crying need of systematic supervision of and instruction in rural communities.

12. Todd believes that pain and soreness in the neck in the region of the tonsils usually arise from diseased tonsils, which also cause neuralgias of the ear, side of head, neck, teeth, gums or antrum. Disturbances of function through pressure on or inflammation of nerves may manifest itself in hoarseness, loss of voice, cough, difficult deglutition, or entrance of food into the trachea, defects in hearing, dyspepsia and disturbed heart action. Such diseased tonsils are not usually large or acutely inflamed.

14. Craig has studied the effects of quinine upon the morphology and life-cycle of the malarial parasite. All varieties of plasmodia react in the same general way to this drug. In fresh specimens Craig noted an initial stimulation of ameboid activity, followed by a decrease in activity, and eventually by a cessation of motion. The protoplasm showed granular degeneration, and fragmentation of the parasite was the end result. Craig insists upon the administration of quinine in divided doses at regular intervals, following a larger initial dose, instead of giving it all in one dose just before sporulation. His reasons for this are that he found quinine able to destroy the plasmodium at every stage of its life-cycle in man, with the possible exception of the sporulating stage. If, on the other hand, only one large dose is given, the plasmodia which survive go on to normal development as soon as the drug is excreted. He refers to over two thousand patients in which he has used this method with success.

In the second part of his paper, Craig describes, with the aid of illustrations, the intracorpuscular conjugation of the parasite. In cases of duration of more than a few days, or in those in which the blood becomes loaded with plasmodia, two forms may be seen uniting within an erythrocyte. These sexually united forms, Craig believes, escape death from medication and lie dormant in the bone marrow or spleen. Their reawakening to activity is the origin of a relapse.

16. From an exhaustive series of experiments Clark concludes that the pseudodiphtheria bacillus or Bacillus Hofmanni belongs to a different species from the true Klebs-Loeffler bacillus.

19. Torrey and Rahe, investigating an opinion of Hess that the top 2 oz. of cream in a quart bottle of milk contain many more bacteria than the subjacent fluid, found (1) the upper 2 oz. of the cream of fresh bottled milk of fair quality contain 50 to 100% more bacteria than an equal amount of the lower cream. In older or more impure milk the lower layers may contain more bacteria than the upper. (2) By removing the top 2 oz. and using the remaining top milk (8 oz.) for infant feeding, there generally results a reduction of from 30 to 50% in the bacterial count.

27. Sedgwick and MacNutt's paper is an interesting collection of mortality statistics from cities which have installed filtration systems for their drinking water. The Mills-Reincke phenomenon is the decrease in mortality from diseases, aside from typhoid, commonly not thought of as being water-borne, for example, pneumonia, pulmonary tuberculosis, diphtheria and infantile diarrhea, which follows the installation of a filter. It is not known whether this decrease is due to improved resistance or to a decrease in the bacteria ingested, or to a combination of the two. At any rate, the problem seems worth investigation.

31. Davis reports three cases from the urine of which he isolated a bacillus resembling, but not identical with, the bacillus of influenza. This bacillus could be grown only in the presence of hemoglobin, and grew best under anerobic conditions. The cases from which it was derived all had more or less pus in the urine. Two of them had joint trouble, although there was no proved relationship between it and their pyuria. [G. G. S.]

2. Nocht and Werner had an opportunity to study a number of cases of malaria which came from Brazil. The parasites resembled the tertian and tropical types except that they were small and caused relatively small changes in the blood cells. These cases showed certain peculiarities in that they presented symptoms on the part of the intestinal tract, lungs and nervous system; also the temperature charts were not characteristic. The peculiar feature was their resistance to quinine even in doses considerably above the usual amount. Methylene blue was tried and found without value. Ehrlich's new antisyphilitic preparation acted well in driving the parasites from the circulation, but it did not prevent relapses. Further work with this preparation may produce better results. [C. F., Jr.]

5. Lazarus, E. *Proteolysis of Anthrax Bacillus.*
6. Dobowatski, K. *The Bacteria which Produce Phenol.*

1. In the region of Tâu Châu there is a micrococcus which attacks the butterfly of the silkworm and destroys it. This author calls it the "red disease" because when grown in excess it assumes a red color. On the destroyed butterflies it gives a distinct red color. Broquet did experimental work to prove that this coccus was the cause of death and not an overgrowth afterwards. This coccus also exists in the laboratory air, etc. The other known silkworm diseases exist in the same district. By destruction of the diseased ones and purification of the air the disease can be cleared up.

3. Bordet and Fally give cultural characteristics and method of isolation, through inoculation of eyes, of the bacillus which causes the disease of diphtheria in poultry. It is a difficult bacillus to grow, as others overgrow it, but by inoculating animals' eyes they obtain it in almost pure culture from the discharge, and from this make cultures. They also report some experimental inoculation work which further supports the claim that this bacillus is the etiological factor in the disease. [C. F., Jr.]

Revue de Médecine.

4. Berthelot. *New Uses for Lactic Acid Bacteriotherapy.*
5. Kabanov. *Edema and Disturbances of the Function of the Sweat Glands in Nephritis.*
6. Gembarski. *A Case of Syphilitic Jaundice.*

1. Hedon's article, from its title, "The Internal Secretion of the Pancreas," at first sight would seem to contradict the theory of the nervous control of glycemia. He admits, of course, that subcutaneous transplantation of a portion of the pancreas, after the remaining glandular tissue has been removed, is sufficient to prevent diabetes. But "the abdominal vasculo-nervous connections of the transplanted fragment remain intact."

In order to study this relation he has performed four experiments. Firstly, the carotid artery and the jugular vein of a depancreatised dog are connected with the pancreatic artery and vein respectively of a sound animal. This procedure fails to reduce the sugar content of the blood or urine of the affected dog. This is one point in favor of the nervous or reflex origin. Secondly, the injection of pancreatic venous blood of a sound dog fails to diminish diabetic tendencies in a depancreatised animal. Thirdly, on the other hand, exsanguination of a depancreatised dog and replacement of the lost fluid by normal blood causes a diminution of glycosuria, which is, however, only temporary. Whether this is due to renal changes, as the author believes, is open to question. Lastly, by a reciprocal anastomosis of the carotids of diabetic and normal dogs, a constant interchange of blood is effected. This produces a gradual decrease in glycemia and glycosuria in the diseased animal, and a corresponding increase of the former without the appearance of the latter in the sound animal. The glycosuria gradually diminishes and after some hours disappears from the diabetic, only to return when connection is severed.

In spite of the last two experiments, the author, who was formerly admittedly a sound adherent of the "internal secretion theory," declares that the regulation of sugar metabolism is undoubtedly the result of a double action, humoral and reflex as well. The former is a most complex mechanism, understood under the name, misleading in its simplicity, of the internal secretion of the pancreas. The latter comprises a central nervous control by means of the pancreatic nerves and the abdominal sympathetic plexus.

3. While the trichocephalus is found in the stools very frequently, the author believes that many conditions may be attributed to their action, when they are found in large quantities in the excreta. These conditions are either local, on the one hand, or general and secondary in nature, on the other. Foremost among the former are ileocolitis and appendicitis. Anemia may result from mucous membrane trauma. Under the latter heading are enumerated many functional central nervous disorders, such as neurasthenia, hystero-neurasthenia, hystero-epilepsy, hemichorea, headache and migraine. Many cases are cited in which symptoms are detailed. The eggs of the parasite were found in profusion in all, and the removal of the supposed etiological factor resulted in complete recovery, or at least in an amelioration of symptoms. The treatment which Stcherbak recommends is that of thymol, given in small doses covering a long period of time. [L. H. S.]

Obituary.

GUSTAV BAUMGARTEN, M.D.

Dr. Gustav Baumgarten, for many years intimately associated with medical progress in St. Louis, has recently died in his seventy-fourth year after a protracted illness. Dr. Baumgarten was born at Clausthal, in Germany, and received his preliminary education there and at Northeim. He came to this country in 1850 and later returned to Germany for special work at Goettingen, Berlin, Prague and Vienna. Returning to St. Louis, he became one of the leading practitioners of that city, and was widely known throughout the entire country. He received the degree of LL.D. from Washington University in 1906, and in 1899 was president of the Association of American Physicians. He was so far identified with America that he served during the Civil War as Assistant Surgeon-General in the Navy. He was editor for a time of the St. Louis *Medical Journal*, and for a good many years was a frequent and illuminating contributor to medical literature. His chief interest was in pathology and therapeutics. His death removes a figure of national prominence in medicine.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED SEPT. 14, 1910.

MCINTOSH, W. P., surgeon. Detailed as member of a Revenue-Cutter Service Retiring Board, Baltimore, Md., Sept. 15, 1910. Sept. 6, 1910.

WERTENBAKER, C. P., surgeon. Granted one month's leave of absence from Sept. 12, 1910.

ROBINSON, D. E., passed assistant surgeon. Granted one month's leave of absence from Sept. 8, 1910.

GWYN, M. K., passed assistant surgeon. Detailed as member of a Revenue-Cutter Service Retiring Board, Baltimore, Md., Sept. 15, 1910. Sept. 6, 1910.

PETTYJOHN, JOSEPH, passed assistant surgeon. Granted one month's leave of absence from Sept. 15, 1910, on account of sickness.

WARNER, H. J., assistant surgeon. Granted seven days' leave of absence from Sept. 17, 1910.

PREBLE, PAUL, assistant surgeon. Granted ten days' leave of absence from Sept. 8, 1910.

GRIMM, R. M., assistant surgeon. Leave of absence for four days' from Sept. 1, 1910, amended to read four days from Sept. 13, 1910.

THOMPSON, LEWIS R., assistant surgeon. Directed to proceed to Chicago, Ill., and report to the medical officer in command for duty and assignment to quarters. Sept. 13, 1910.

BINGHAM, E. O., acting assistant surgeon. Granted fifteen days' extension of leave of absence from Aug. 16, 1910, on account of sickness.

HORNING, HENRY, acting assistant surgeon. Granted seven days' leave of absence from Sept. 6, 1910, under paragraph 210, Service Regulations.

HUME, LEA, acting assistant surgeon. Granted five days' leave of absence from Aug. 1, 1910.

MASON, WILLIAM C., acting assistant surgeon. Granted seven days' leave of absence from Sept. 18, 1910.

SINCLAIR, A. N., acting assistant surgeon. Granted four days' leave of absence from Aug. 23, 1910, under paragraph 210, Service Regulations.

WALLACE, C. R., acting assistant surgeon. Granted nineteen days' extension of leave of absence from Aug. 3, 1910, on account of sickness.

WALKLEY, W. S., acting assistant surgeon. Granted three days' leave of absence from Sept. 16, 1910.

STERNS, C. O., pharmacist. Granted twenty-six days' leave of absence from Sept. 12, 1910.

APPOINTMENT.

DR. LEWIS R. THOMPSON commissioned (recess) an assistant surgeon in the Public Health and Marine-Hospital Service. Sept. 6, 1910.

REINSTATEMENT.

F. A. STUMP reinstated as a pharmacist of the third class. Sept. 9, 1910.

BOARDS CONVENED.

Board of medical officers convened to meet at the Marine Hospital, San Francisco, Cal., Sept. 21, 1910, for the purpose of making physical examinations of officers of the Revenue-Cutter Service. Detail for the board: Passed assistant surgeon R. E. Ebersole, chairman; assistant surgeon R. A. Kearney, recorder. Sept. 9, 1910.

Board of medical officers convened to meet at the Marine Hospital, Baltimore, Md., Sept. 21, 1910, for the purpose of making physical examinations of officers of the Revenue-Cutter Service. Detail for the board: Surgeon W. P. McIntosh, chairman; passed assistant surgeon M. K. Gwyn, recorder. Sept. 9, 1910.

SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY. — The Fall Meeting will be held in Sprague Hall, Medical Library, Boston, on Wednesday, Oct. 5, 1910, at one o'clock. The following papers will be read and discussed: 1. "The Preservation of Medico-Legal Evidence," Fred E. Jones, M.D., Medical Examiner, of Quincy; Prof. William F. Whitney, of Harvard Medical School. 2. "A Close Gunshot Wound without Powder Marks," H. M. Cutts, M.D., Medical Examiner, of Brookline. 3. "How Far May a Medical Examiner Go in Employing Expert Assistance?" W. N. Cowles, M.D., Associate Medical Examiner, of Ayer.

OLIVER H. HOWE, M.D.,
Recording Secretary.

COHASSET, Sept. 27, 1910.

RECENT DEATHS.

DR. G. HOWARD JONES, of Brookline, Mass., died Sept. 15, at Harrison, Me. Dr. Jones was born in Boston, in 1844, and was graduated at the Harvard Medical School in 1872. He served through the Civil War as Assistant Surgeon in the Fifth Massachusetts Regiment.

Dr. WILLIAM G. DAGGETT, of New Haven, has recently died following an operation for appendicitis. Dr. Daggett was graduated from Yale College in 1880, and from the Medical School of the University of Pennsylvania four years later. He had been lecturer on clinical medicine for a number of years at the Yale Medical School, and was one of the foremost physicians of New Haven.

DR. JOHN BEVERLY CROWELL, of East Orange, N. J., died suddenly from cardiac disease on Sept. 20. He was sixty years old and a graduate of the University of the City of New York and the College of Physicians and Surgeons, New York

DR. JOHN P. PHILLIPS, who died at his home in New Haven, Conn., on Sept. 20, at the age of seventy-seven years, served as surgeon with the Eleventh New York Regiment in the Civil War, receiving a medal from the state of New York in recognition of his services. Dr. Phillips was graduated from Columbia College in 1856, and three years later from the New York Medical College.

DR. WILLIAM FREDERICK HOLTHAUSEN, of Brooklyn, N. Y., was killed in a railroad collision in Indiana, on Sept. 24. His death is peculiarly tragic, as he was to have been married on the 26th, and was on his way to the home of his fiancée at Kokomo, Ind. Dr. Holthausen was a native of Brooklyn and thirty years of age. He was a graduate of the School of Mines, Columbia University, and was graduated from the Medical Department of Columbia in 1904.

Address.

IMMUNITY WITH SPECIAL REFERENCE TO VACCINE THERAPY.*

BY TIMOTHY LEARY, M.D.,
Professor of Pathology, Tufts Medical School.

It is my purpose to review hastily the progress of our studies in immunity in order to make plain why that portion of the scientific medical world which has been interested in the *practical* application of immune principles to disease conditions welcomed the work of Wright as opening up a new avenue of approach toward the elucidation of a problem whose solution seemed impossible from the viewpoints which were held at the moment when his work was presented.

The student of pathology learns early in his career that the morphological tissue response to insults is limited to a few fundamental possibilities. Details of the reaction may be infinitely varied, but the basic variations are few, no matter what the character of the injury may be. Further, by artificial stimuli we have not succeeded in adding to the varieties of response which are exhibited against natural stimuli.

It seems to be equally true of immunizing responses to stimuli that the types of response are relatively few.

It should be made clear that the laboratory worker in immunity, when he makes a step in progress, does nothing new or strange. He invents nothing. He evolves no new principles. He studies nature and endeavors to wrest from her the secret of her methods of rendering harmless the parasitic organisms or their products which find themselves in the living animal body. Studies of immunity will be complete when we have laid bare all of these methods. The successful artificial method of attacking an infectious process depends upon as close an imitation as possible of nature's method of accomplishing the same thing.

Practical progress in specific therapy of human infectious processes really began with the discovery of diphtheria antitoxin. First came the demonstration that the diphtheria bacillus produced a soluble toxin; that bouillon in which the diphtheria bacillus had been grown for several days had acquired a definite poisoning power for animals even after the diphtheria bacilli which produced the toxin had been filtered off; that a measurable quantity of this bouillon, or diphtheria *toxin*, as it is called, would kill a guinea pig of a certain weight. Next came the discovery that an animal into whose body less than a fatal dose had been injected developed after a time the power to overcome what would be a fatal dose for an untreated animal of its weight. The injection of the non-fatal dose of toxin had stimulated the formation of an antitoxin. This antitoxin, produced in various tissues, is delivered into the blood stream, where it is found in the globulins of the blood serum. It was a simple practical problem to produce this substance in quantity in large animals, from whom large quantities of blood could be removed without harm, and the serum or its globulins made use of to supply the deficiency in antitoxin production in human beings undergoing infection with the diphtheria bacillus, or even to prevent infection in those exposed, by surcharging their tissues with antitoxin and thus making the ground unfavorable for the diphtheria bacillus.

It should be noted that diphtheria antitoxin has no important direct influence on the diphtheria bacillus. It acts solely by neutralizing the toxins of the organism, which, thus disarmed, falls an easy prey to other protective agencies.

The discovery of diphtheria antitoxin led to the hope that similar sera could be produced which would have as happy an influence on other infectious processes. It was soon learned, however, that few other bacteria than the diphtheria bacillus produce a soluble toxin in quantity. A study of infection with the diphtheria bacillus shows it to be an almost pure toxemia. The bacteria are limited to the local lesions in the throat. Here they manufacture their toxins, which are carried in the blood stream to all parts of the body, producing toxic degenerations of the so-called parenchymatous organs and the nerve trunks. The lesions which lead to death are thus produced largely at points distant from the region where the toxins are elaborated. The tetanus bacillus is the only other organism among the important pathogenic bacteria which produces mainly a soluble toxin and whose lesions largely arise at a distance from the bacteria, as in the case of diphtheria.

With the great group of other pathogenic bacteria, the story is a distinctively different one. General processes, when they arise, do so as a result of the invasion of the blood stream by the bacteria (bacteremia), and the organisms are carried to all parts of the body. The staphylococcus, streptococcus and pneumococcus, for example, depend for their activity in great part, not upon soluble toxins, but upon toxins (endotoxins) which are limited to the bodies of the bacteria. The problem in these cases is not the simple one of neutralizing toxins, but the more complex one of destroying bacteria as well.

Investigation has shown that bacteria which enter the blood stream may be destroyed by substances present in the blood serum which produce a digestion — a solution (bacteriolysis) — of the organisms. This phenomenon depends upon the interaction of two substances. The first of these is a specific body, — the so-called amboceptor, — a distinct immune body which may be increased in quantity at will in susceptible animals, just as diphtheria antitoxin may be produced experimentally in quantity. If this body were capable alone of the destruction of bacteria, our problem would be solved. Unfortunately, however, the actual destruction of bacteria (bacteriolysis) is dependent upon the interaction with it of a second body — the ferment which completes the solution of bacterial cells and which is known as complement. Complement is an unstable body, with little resistance to heat, and disappears rapidly

* Read at meeting of Rhode Island State Medical Society, June, 1910.

from blood serum which is kept. It is present in the blood serum of all living animals, although its quantity may show marked variations. A slight disturbance, such as a headache, may diminish its quantity markedly, and we have discovered as yet no means of increasing the amount normally present to any considerable degree. Hygienic living, with abundant fresh air and good food, will keep its measure at a high par, but even under these conditions slightly untoward circumstances will rapidly lower the amount.

The individual who is undergoing infection with the typhoid bacillus, for example, is producing sufficient amboceptor for his needs. What his blood lacks is complement, and we as yet have no means of artificially supplying this need. Antisera rich in amboceptor may be readily produced, but the real need of the infected individual — complement — we cannot provide for.

For these reasons the so-called anti-bacterial or bacteriolytic sera are, as a whole, failures. An apparent brilliant exception, Flexner's anti-meningococcic serum, belongs in a class by itself because of the character of the meningococcus. This organism is one of a group of bacteria which undergo solution readily, probably even in the absence of complement. Rosenow has shown, and our own experience has confirmed this, that the group of organisms to which the meningococcus belongs will undergo solution in any normal serum, even in a serum which has little bacteriolytic influence on other bacteria, and sometimes solution of the bacterial bodies will occur in physiological salt solution. A specific serum against this organism belongs, therefore, in a special class and does not seriously modify the statement that bacteriolytic sera as a whole are failures.

Another method of dealing with infection was suggested by Metchnikoff's observation that the animal body protected itself in part against the invasion of pathogenic bacteria by means of active cell processes. He observed that, in the lower animals, certain infections were held in check or overcome by the action of motile cells, which took the invading bacteria into their bodies and destroyed them by a process of intracellular digestion (phagocytosis). The most active phagocytic cell in the human body is the polynuclear leucocyte. It was shown that the number of leucocytes in the circulating blood could be increased by the use of preparations containing nucleic acid. Substances such as yeast, rich in nucleins, were, therefore, used as a means of combating infection, but without marked influence on the processes.

Thus matters stood when A. E. Wright published his first practical results from bacterial vaccination. From 1892 to 1902, efforts in the direction of specific therapy had resulted in no signal advance. Our study of nature's methods had disclosed no new avenue of approach toward the solution of the problem, and we could not imitate nature successfully along the old ones.

The new facts which Wright brought out were (1) that the cellular destruction of bacteria (phagocytosis) does not depend solely on cell activity; that before bacteria are taken into the bodies of cells they must be acted upon by substances present in the blood serum (opsonins). White corpuscles washed free from serum are not attracted by bacteria with which they are brought in contact and will not, therefore, show phagocytic activity. The addition of a small amount of normal serum to the mixture of bacteria and washed white cells will be followed promptly by the familiar picture of phagocytosis.

(2) That the injection of suspensions of dead or modified bacteria (bacterial vaccines) into infected individuals would provoke the formation of antibodies more or less specific in character against the bacteria used for making the suspensions. The use of suspensions of modified bacteria in the *prophylaxis* of disease has been practised since the earliest years of bacteriology. The new step was the demonstration of their value in treatment of infections already established. The response to their injection is indicated not only by the formation of opsonins, but also by the production of other antibodies.

Wright's work has opened up a new world of possibilities in the struggle with infection. It is producing practical results in the treatment of infections which could not be hoped for a few years ago, and it has given the research worker a new basis from which to attack the problems of immunity.

THE PRINCIPLES OF VACCINE THERAPY.

It should be said in the beginning that the opsonic index as a measure of the immunity response under vaccination is looked upon in this country as inaccurate. It requires a complicated technic, has many sources of error, and in our experience the results obtained are unsatisfactory. It has a value in the diagnosis of obscure conditions.

Wright believes that a proper therapeutic dose of vaccine in an infected individual is followed by a period of intoxication, accompanied by a diminution in antibodies (negative phase), followed by a stimulation of the immunizing machinery and the production of an increased amount of antibodies (positive phase). Theoretically, it should be possible to bring about the production of surges of antibody production, each wave higher than the preceding one, with progressive beneficial results to the infected individual. Wright, in his early work, insisted that, in order to provoke a positive response to vaccination, it was necessary to inject a sufficient dose to produce at first intoxication (negative phase). Our experience and that of others has shown that the ideal immunizing response can be produced without the toxic negative phase. Physiological doses of vaccines should be followed by an immediate production of antibodies without toxic action.

Wright believes that the individual who is undergoing infection with a carbuncle does not produce sufficient antibodies because the toxins of the staphylococcus are not being absorbed from the local lesions, owing to the disturbed blood vascular circulation and the obstructed lymphatic

drainage of the infected region. Such an individual, however, has general malaise and frequently shows temperature, both of which should be accepted as evidence of toxic absorption. A more reasonable explanation, it seems to me, is that, while absorption of abundant toxic material is taking place, the character of the toxic material is not such as to stimulate the defensive forces. It is possible that there is some selective action in absorption, so that certain beneficial stimulating substances may not be taken up by the lymph stream from the focus of infection.

Another reasonable explanation rests on a belief in the local character of many immunity responses. It has been generally accepted that the immune bodies are produced almost wholly by the blood-making (hemapoietic) organs, and thence delivered into the blood stream. This theory fails to take into account the special immunity which certain tissues exhibit against infection. Most important among these are the muscles. Voluntary muscle is recognized as almost completely immune to tuberculosis, and undergoes infection with pus-producing organisms only after the intermuscular connective tissue has been overwhelmed. We recommend the injection of vaccines into muscle or into the intermuscular connective tissue. The satisfactory response which is obtained, we believe to be due in part to the awakening of the defensive metabolism of the muscle system by a stimulus differing in character from the toxic material absorbed from the local focus of infection.[1]

If the school of vaccine therapy does no more than to call attention to the muscle system as an important factor in the immune mechanism, it will have justified its existence.

Wright believes that an interval of at least seventy-two hours should elapse between inoculations of vaccines because of the toxic-negative phase following each inoculation. Early in our experience it became evident that, with proper dosage, the negative phase could be eliminated. The immunity response began to appear almost immediately following the injection of a physiological dose of vaccine. We have, therefore, shortened the interval between doses markedly, particularly in ugly local or in general infections.

Wright advocated the exposure of the suspensions of bacteria used in making vaccines to 60° C. for one hour for the purpose of killing. The immune response to the injection of vaccines is at least in part a specific one. This may be supplemented by more general phenomena (see staphylococcus below), but the object sought is an increased resistance to the specific organism which is producing the infection in a given case. Such an increased resistance means the formation of antibodies against the specific proteins of the bacterium. Bacterial proteins as well as others lose their specific character by exposure to high temperatures or by prolonged exposure to low temperature. We have, therefore, gradually shortened the time of exposure of such suspensions to a point where the organisms are just killed. We believe that our greatest contribution to vaccine therapy has been the modification of the killing method. Other methods of killing than by heat (galactose, ether, etc.) have since been advocated, in an effort to preserve the specificity of the bacterial proteins intact.

Staphylococcus Aureus vaccine, in addition to provoking the ordinary specific immunizing response, seems to possess the power of stimulating an increase in general resistance. Merrick,[2] who treated a series of infants suffering from furunculosis, calls attention to the fact that the children not only recovered from the boils, but their general nutrition became so improved after treatment that, from a condition of emaciation, they speedily became the best-nourished and most-resistant children in the institution.

GENERAL INFECTIONS.

The objections to the use of vaccines in infectious conditions seem to focus themselves against their use in general infections. They will, therefore, be considered here. The general harmlessness of vaccines is indicated by the results in two cases of infection in which, through error, 10 ccm. of staphylococcus pyogenes aureus vaccine containing 10,000,000,000 organisms were injected at one time as an initial dose. This is forty times the standard initial dose. In one case no untoward symptoms appeared. In the second there was a temporary collapse, with prompt response to heat and stimulation. There are few powerful drugs in the Pharmacopeia which could be used with such disregard for dosage without serious results.

The most obvious objection to the use of vaccines in general infections is that the patient is undergoing extreme intoxication and that the injection of vaccines will but add to this intoxication. I have called attention to our theory of muscle immunity, and to the fact that physiological doses of vaccines are not followed by a toxic (negative) phase. The dose of vaccine used in pneumonia, for example, contains fewer organisms than will be found in a few out of the myriads of infected air sacs of the lung in this disease. The dosage is so infinitesimal, and its toxic effect is so slight, if any, that it is not measurable. As evidence that even much larger doses are at least harmless, I might cite the case of a child of seven years undergoing an infection with pneumonia, with a temperature of 103 and extreme meningeal symptoms, into whose body was injected as an initial dose, 8 ccm. of pneumococcus vaccine containing 1,600,000,000 pneumococci. The standard dose for adults is 8 minims, or 100,000,000 pneumococci. This child receiving sixteen times the adult dose of vaccine not only did not show harmful results, but began to mend shortly following the initial injection and recovered under daily injections of several times the usual adult dose. A second child with pneumococcus meningitis showed prompt diminution

[1] Since this paper was read, Theobald Smith, in a paper on "The Experimental Basis for Vaccine Therapy," read before The Massachusetts Medical Society, June 8, 1910, called attention to the possible local character of immune body production, and suggested vaccination in different sites as a means of awakening these local mechanisms.

[2] Ann. Gynec. and Pediat., September, 1908.

in the number of pneumococci in the cerebrospinal fluid, and sharp amelioration of symptoms accompanying the use of four to eight times the standard adult dose of pneumococcus vaccine. Death occurred from exhaustion, the meningitis having followed a series of children's diseases with bronchopneumonia,

Another objection offered to the use of vaccines in general infections is that vaccines stimulate the production of bacteriolytic substances and that these substances may kill many bacteria and set free their toxins, thus overwhelming the body with toxic products. Flexner's antimeningococcic serum is a bacteriolytic serum about whose value there is little question. It is injected into the subdural space of children who are suffering from extreme intoxication with the meningococcus and its products in a region which is most sensitive to these products. Its injection is followed by the immediate action of its bacteriolytic substances on the meningococci with which they come in contact. Examination of the fluid shows a prompt and extreme diminution in the number of meningococci, and yet I have never seen reported harmful results related to the sudden setting free of their toxins. Following the injection of vaccines, the theoretical evolution of bacteriolytic substances, if occurring, must take place slowly and gradually. There is not an explosive setting free of these substances such as the injection of meningococcus serum brings about, and the effect, if any, must be less than that shown in meningitis, which is practically negligible.

It may be argued that Flexner's serum contains anti-endotoxins capable of neutralizing the toxins of the meningococcus when set free. If this is true, it is the first practical anti-endotoxic serum which has been produced (Besredka's anti-endotoxic typhoid serum has only experimental interest) and Flexner makes no claims of anti-endotoxic properties. Even though such claims are made, the prompt recovery of a child into whose subdural space normal horse serum was injected in an emergency when Flexner's serum could not be obtained would suggest that danger from products of bacteriolytic action is not serious.[3]

A third objection is that patients undergoing infection are in an anaphylactic state; are, therefore, hypersusceptible to intoxication. With chronic infections such as tuberculosis this danger apparently exists, and for that reason I believe the use of tuberculin in treatment should be carried out with extreme care. We have never seen evidence of its existence in the acuter conditions produced by other bacteria. It takes time for the establishment of anaphylaxis, and the general infections with their sudden onset should be largely free from such danger. Anaphylaxis is a purely theoretical danger, as is evidenced by the infrequency of serious results following the use of diphtheria antitoxin. If guinea-pig experiments with horse serum gave a true picture of what was to be expected in human beings, the use of diphtheria antitoxin would be so limited on account of anaphylaxis that its value would be very questionable. As I have said elsewhere, theoretical considerations of this sort must yield to the facts of experience.

[3] Personal communication, Dr. S. P. Beebe.

DISTINCTION BETWEEN GENERAL AND LOCAL INFECTION.

The old belief in bacteriology was that there was a sharp dividing line between general and local infections. More recent work has demonstrated that such a line does not exist. Every case of typhoid fever is a general infection, as is every case of pneumonia, endocarditis, meningitis and most of the acute septic processes. It has been demonstrated that every case of erysipelas starts in as a general infection. Recovery from these conditions is brought about, first, by the localization of the infection and then by the destruction of the bacteria in the local focus.

In streptococcus general infections French workers found that the injection of turpentine into skeletal muscle, if successful in provoking a local abscess, was associated with the focalization of the infection, which could then be handled as a local process. If the patient's condition were such that local abscess formation did not occur, then the treatment was not successful.

Our grandfathers, probably with the same end in view, thrust setons through skin, subcutaneous tissue and muscle with apparently similar results.

Some of our results with general streptococcus sepsis were illuminating in much the same direction. We were given opportunity to treat cases of puerperal sepsis in which all clinical expedients had been exhausted and in which the outlook was hopeless. In a number of these cases a prompt drop in temperature followed the exhibition of vaccine. In this group I am somewhat skeptical as to the influence of the vaccine, since other factors may have played a part. In many of the other cases there was a progressive forcing downward of both pulse and temperature, which reached normal after several days. In certain of these cases local formation of pus, either in the uterus or else in muscle or subcutaneous tissue, occurred from one to three days after the temperature had reached normal. The further treatment of these cases consisted in the simple problem of caring for a local infection.

The localization of a general infection following the injection of turpentine into muscle by the French, the introductions of setons according to the older surgery or the injection of specific vaccines according to the newer procedures, first drew our attention to the apparently important part which local defensive mechanisms, and notably muscle, played in increasing general resistance.[4]

It is not my intention to speak of the use of vaccines in pneumonia until we have carefully collated the data obtained from reports of work

[4] I do not want to be misunderstood as claiming that we have solved the problem of streptococcus general sepsis. We believe that we have saved many cases of puerperal general sepsis which otherwise, according to the best views of able practitioners and consultants, would have died. Some cases, notably those whose resistance was gone, have died. In cases where the resisting mechanism was still capable of stimulation, the use of an autogenous vaccine killed at 60° C. for fifteen to twenty minutes, and injected at frequent intervals in physiologic doses, has furnished remarkably good results, and we have never seen evidence of harm.

during the past year. We have furnished pneumococcus vaccine for about fifteen hundred cases, but in spite of the fact that we made the reports so simple that a few minutes would suffice for recording the desired data, the return of these reports is slow. The evidence seems to predominate that this vaccine is a distinct addition to our armamentarium.

LIMITATIONS OF THE VACCINE TREATMENT.

Vaccine treatment in surgical conditions does not do away with the necessity for intelligent surgery. In an accumulation of pus the opsonins and other antibodies which are formed in response to bacterial vaccination cannot be delivered from the blood stream into the pus. In thick pus currents are sluggish or absent and the transmission of antibodies into the central part of the mass of pus must be interfered with. Contact with the bacteria is prevented and, therefore, the organisms are unaffected. It is essential that drainage be established. If this is done, the bacteria along the granulating wall will be quickly destroyed and healing be more rapid than surgical measures alone could bring about. Vaccine therapy does not supplant, but supplements, intelligent surgery.

With infections in certain locations, particularly along some mucous surfaces, vaccine therapy is less successful than elsewhere. Gonococcus vaccine, for example, has little influence on urethral infections in our experience, but a freshly prepared gonococcus vaccine made from first cultures from fresh cases gives such prompt and constant results in gonorrheal rheumatism that we are led to doubt the diagnosis in cases which do not respond. Our doubts have been justified in all cases which did not respond in a considerable series.

In infections of the kidneys, where there is a local irritant in the form of a stone, or where drainage is interfered with, vaccine treatment has little value. If the colon bacillus is the infecting agent, intoxication will be relieved and fever eliminated, but local infection will persist.

In the bladder, if residual urine is constantly present, vaccine therapy is only palliative, since the chronic irritation of the bladder mucosa by products of the saprophytic bacteria usually present will favor the continuation of the process.

In bacteriuria, vaccines have little value. Bacteriuria is marked by the growth of organisms in the urine, as in a culture medium. There is no infection. The bacterium and the human being are growing in harmony. No means of breaking this symbiosis has as yet been discovered for most organisms. Infection, if it exists, can be overcome, but the symbiosis persists.

NECESSITY FOR RESISTING ABILITY.

Diphtheria antitoxin confers a passive immunity. It requires the patient only to furnish a circulation for its distribution. When it comes in contact with diphtheria toxin, it neutralizes it without assistance from the patient. The defensive mechanism of the patient is left free to cope with the diphtheria bacilli at the point of infection.

Bacterial vaccines require the active co-operation of the patient. Vaccines, as far as we know, accomplish nothing directly except to stimulate the lagging immunizing machinery to produce needed antibodies. It is, therefore, essential that the defensive mechanism be in condition to respond to this stimulation if good results are to be obtained. For lack of this preparedness, fulminating cases of streptococcus peritonitis, for example, in which the septic absorption is extreme, do not usually respond to treatment, while slower infections do.

PRACTICAL APPLICATION.

It is not possible nor desirable to go into detail about practical procedures in this rather lengthy paper. Suffice it to say that the group of infections for which the average practitioner desires to use vaccine therapy, while comprehensive, is due to the activity of relatively few organisms. *Staphylococcus* vaccine is now accepted as the standard method of treatment of local conditions due to this organism. In general infections results are less satisfactory because, I believe, such a general process is usually a pyemia, and the organisms in a pyemia are contained in masses of clot and less accessible to the antibodies which may be formed.

Of *streptococcus* general infections I have spoken. Among local infections, erysipelas responds in most cases with promptness. This is particularly true if an autogenous vaccine can be obtained. Local septic processes also respond promptly.

The empirical use of vaccines made from autogenous throat cultures, and containing usually a mixture of the pneumococcus and streptococcus, has given usually prompt relief of pain and a bettering of other symptoms in a large percentage of the cases of rheumatism treated.

The treatment of the associated infection in tuberculosis with autogenous vaccines in which the streptococcus and pneumococcus usually predominate is accompanied by diminution of temperature and relief of cough and night sweats, followed by increase of weight.

Pneumococcus and *gonococcus* processes have been mentioned.

The frequency with which *B. coli* is an infecting agent has only been fully appreciated since vaccine therapy has been inaugurated. The colon bacillus may give rise to marked toxic symptoms from a relatively slight infection. Such intoxication can be relieved usually within a few hours. Genito-urinary infections due to this organism have been considered. The response in bladder infections, where well drained, is rapid and permanent where re-infection can be guarded against. In typhoid fever the so-called exhaustion which arises in the late stages and which leads frequently to a fatal issue is apparently due to B. coli infection. An autogenous vaccine made from the feces has in three cases with us been followed by a prompt disappearance of the septic temperature and rapid progress to convalescence. In membranous colitis an amelioration of symptoms persists while the vaccine is used, but prompt relapse usually follows its withdrawal. B. coli vaccine prepared from the urine of cystitis asso-

ciated with rheumatism or rheumatoid conditions has not only cleared up the cystitis, but has also relieved the rheumatoid symptoms promptly in a small series of cases with us. B. coli vaccine should always be prepared directly from the patient's organism and should be used in small doses. The initial dose should not be more than 25,000,000, cautiously increased.

Tuberculin.—No final judgment of the value of any agent used in the treatment of tuberculosis can be made unless its practice has been followed for many years. I am, therefore, only hazarding an opinion of the value of tuberculin from our limited observation. I believe that tuberculin in proper doses is a valuable addition to standard methods of treatment. Its use, however, is associated with dangers which make extreme caution necessary in its exhibition. Wright's method, which calls for an extremely small dose at weekly intervals, seems to eliminate all dangers of over dosage.

I hope that the time is not far distant when local laboratories will properly develop the field of vaccine therapy. The observer in this field requires an accurate and extensive knowledge of the small group of organisms which play a part in most infectious processes. With this mental equipment a knowledge of the technic of vaccine production and therapy can be quickly developed. There is no reason why autogenous vaccines cannot be produced in the larger hospitals and medical centers of the community. I look forward to the day when an equipment in this direction will be expected of the local pathologist and bacteriologist.

Vaccine therapy is in its infancy. It is but a step in progress toward the specific therapy of infectious processes for which the medical world has been anxiously waiting. I trust that I have made clear my reasons for believing that, through the new viewpoint it has opened, a way to the solution of these problems may be made possible.

TYPES OF GRAVES' DISEASE.

BY J. G. MUMFORD, M.D., BOSTON.

The types of Graves' disease are so various, and the special symptoms, or lack of symptoms, so puzzling, that it is well for a student of the subject frequently to compare cases, especially that he may bring home to himself the possible and serious outcome of conditions which often appear trivial and more often are obscure. Frequently it happens that the frank, acute cases, with the classical symptoms, are cured by any treatment, and by no treatment even. Sometimes it occurs that a case apparently trifling, perhaps running an easy, chronic course, suddenly becomes worse and dies in spite of all treatment.

Here are two dissimilar cases, a typical case and an atypical case, both of which occurred in my practice, both of which caused me the greatest anxiety and taught me new lessons regarding the nature of this interesting ailment.

Case 1 was that of Mrs. A. S., a woman of forty-two. She had behind her a long surgical history, — operations for salpingitis, for retroperitoneal cyst, for ovaritis, — but in spite of these serious diseases and operations, which occupied many years of her younger life, she came out strong and vigorous. At the age of thirty-seven, however, she consulted her physician for what appeared to be a trifling heart lesion, for she found herself troubled with occasional dyspnea on exertion. Her physician discovered a slight mitral leak and some dilatation of the heart. Careful treatment and prolonged rest resulted in no benefit; gradually there developed further a constant distressing dyspepsia, pain and nausea after eating and a state of continual apprehension. These symptoms persisted for two years, when there developed further a mild, bilateral tremor of the fingers. At this stage she consulted me, on the advice of her physician, and I was able to suggest the diagnosis of exophthalmic goiter. Even so, the diagnosis was by no means assured, for no enlargement of the thyroid was evident, nor were there marked eye symptoms, while the heart rate rarely went above 80. We continued to treat her as a cardiac case only — bearing in mind the possibility of Graves' disease — for another year, when within a month there developed a series of characteristic symptoms: the thyroid gland became enlarged, with a typical thrill; the eyes gradually became prominent, with lagging of both lids and widening of the palpebral fissure; and tachycardia became pronounced, the rate of the heart ranging between 110 and 130.

Here was a case which, in spite of its gradual onset, seemed suitable for immediate and vigorous medical treatment. Accordingly, we instituted the use of hydrobromate of quinin, neutral, in 5-gr. capsules, three times a day, and continued the medication without intermission for fifteen months. During the early months of treatment the patient experienced great relief; her apprehension vanished, her thyroid tumor became somewhat smaller, the heart action became slower and her general sense of improvement marked. Such was her state twelve months after the beginning of the quinin treatment. She was not well, however, and her condition of instability became especially apparent at that time through the accident of a serious grief; a favorite sister became ill, and, after a month's extreme suffering, died, under the constant watchfulness of our patient. The strain and anxiety of this experience renewed at once, and markedly, the exophthalmic symptoms. Within a very few weeks, from the state of quiescence I have described, all her discomforts reappeared; the eyes became prominent and anxious, with their associated abnormal lid phenomena; her tachycardia returned; the heart became irregular; dyspnea became extreme; she was troubled with a constant diarrhea and distaste for food; profuse sweating became pronounced; the tremor returned in force; and the right lobe of the thyroid rapidly doubled in size.

Now the case presented all of the typical

symptoms of acute Graves' disease and demanded, apparently, most energetic treatment. Fortunately, during the whole of this period she had been under constant medical care and I had seen her myself once a month for more than a year. The hydrobromate of quinin appeared to be no longer useful, and, in view of the rapid development of her acute symptoms, it seemed wise to me to undertake a radical operation; at the same time, in view of her alarming psychic state, I made every attempt to bring her to the operation in a calm frame of mind. I believe firmly in the value of Crile's suggestion regarding psychic influences in acute Graves' disease, and in the importance of bringing the patient to operation practically without her knowledge. In the present case I followed the plan which I always institute in similar acute cases. The probability of our doing an operation was explained to the patient and her consent to it was secured, as well as the consent of her relatives, but the exact time of the operation was not set, nor was the operation explained to her as inevitable. I sent her to a quiet private hospital, confined her to her room, with a congenial nurse, and kept her there, resting and closely observed, for ten days. She spent her time in bed. I was able to relieve the sleeplessness from which she suffered by the liberal use of bromide of strontium, and, through the inhalation of various volatile oils and colognes, to suggest to her the possibility of improvement. During those ten days she was treated every morning by inhaling either nitrous oxid, eucalyptus, alcohol, spirits of camphor, ether or cologne, all in small, harmless amounts and freely mixed with air. In this way she acquired the idea of taking inhalations without the slightest terror or distress.

The principle of this treatment, as enunciated by Crile, rests on the following proposition: We know that the acute phenomena of Graves' disease are due to the abundant outpouring of the thyroid gland secretion into the lymphatics and so into the general circulation; we know that this outpouring can be increased by such stimuli as fear, anxiety and even mirth, but fear and anxiety are especially deleterious. Clinical evidence shows that the ordinary preparation for operation and the giving of ether have, through the stimulus of fear, more than once killed a patient, from the sudden resulting outpouring of thyroid intoxicants, without any operation having been done. If, then, we can bring the patient to the operation, can produce anesthesia and can operate without altering the equanimity of the patient's mental attitude, we are convinced that we then operate under the most favorable conditions.

I followed this method with the patient under discussion. On the morning set apart for the operation she realized no change in the ordinary routine. She was, indeed, given a hypodermic of morphia, but she had been given hypodermics of sterilized water daily, so that a hypodermic of morphia impressed her mind not at all. An hour after the hypodermic, when she was in a calm and untroubled state, I myself, as had been my custom, entered her room and proceeded with the anesthetic, giving her first a few whiffs of cologne, then an abundant inhalation of nitrous oxid, with a little oxygen, and then, when consciousness was gone, had the anesthesia carried on by ether. This was more than a year ago. My present custom is to carry the patient through the operation with nitrous oxid and oxygen, as I am convinced that thus her resistance can be kept nearest to its normal. The patient was carried, anesthetized, to the operating room, and these interesting facts were noted. Before taking her anesthetic her pulse had been 110; when completely anesthetized her pulse was 112; during the removal of the gland her pulse varied between 100 and 110; half an hour after her return to her room, and while recovering from the anesthetic, her pulse reached 120, but three hours later it had fallen to 90.

This is in notable contrast with the ordinary experience of bringing a terrified patient to the operation, when during that operation we note a steadily rising pulse and a condition often of great gravity before the recovery from ether.

The operation itself in the present case was a simple one; it consisted in removing the left lobe of the thyroid, stripping the posterior capsule after the method of C. H. Mayo, in the removal of the isthmus and the removal of about one third of the right lobe.

After the operation, and with the patient's recovery from ether, all acute interest in the case ceased; though one was struck, as one always is in satisfactory cases, to observe her rapid and complete recovery of health. The first noticeable change was the loss of peevish irritability which had characterized her before. She was relatively calm and tranquil after the operation, and two days later had ceased entirely to complain of any operative sore throat and pain in her neck. Coincidently, one observed a steadying of the pulse and a gradual decline in its rate; the tremor also abated rapidly; dyspnea was never again observed; the sweating disappeared, and at the end of ten days her digestive disorders were greatly improved. The wound healed promptly and never disturbed us. The most noticeable fact, however, about this case, as about all successful cases, was the calm, tranquil and happy attitude of the patient herself. One may not in words clearly define this change, but it is so rapid and so striking in all successful cases that it suggests the relief brought by the timely and appropriate use of morphia to a person in pain and terror. It is the reverse of euthanasia; it is the confident return to a cheerful and comfortable life.

The operation I have described was done some eight months ago, and I have seen the patient four times since she left the hospital. It is too early as yet to pronounce her permanently cured; indeed, one symptom still remains, a slight exophthalmos, but in all other respects she appears and feels absolutely well and goes about her work in life with a vigor and a cheerfulness which she had not known for five years.

This case, in its later developments, was a

typical acute Graves', and in its ready yielding to treatment illustrates admirably the value of operation in proper cases. In no way was it especially remarkable except in the long and gradual onset of the symptoms and in the sudden accession of serious symptoms on the experience of a depressing grief.

Case 2 was atypical: Mrs. T. B. was a vigorous young woman, of active habits, some thirty-two years of age, and the mother of four children. With the exception of her obstetrical history, there was nothing in her past life of any special significance. She had always been regarded as peculiarly sane and well-balanced. Some two years before I saw her she suddenly became extremely nervous; within a week she took on symptoms that suggested to her physician a rapid neurotic breakdown; she was sleepless, fretful, irritable and almost impossible to live with, as her friends asserted. Within a week after the surprising development of these symptoms her physician discovered a marked tumor of the thyroid gland. There was no other evidence of hyperthyroidism, with the exception of the nervousness; there was no exophthalmos, no tachycardia or palpitation, no tremor, no digestive disturbance, no sweating; in fact, the diagnosis was founded almost solely on the nervousness and the rapidly enlarging thyroid.

This patient's physician had the courage of his convictions, and his convictions were sound and accurate. Without stopping to employ drugs, and without waiting to see the development of the case, he proceeded at once to a surgical operation, and his surgical activity seems to have been justified by the results. He removed the whole of the left lobe of the thyroid, leaving, however, the isthmus, with a considerable pyramidal lobe, and the whole of the right lobe. The lobe removed was much the most affected; those parts which were left seemed to be but slightly hypertrophied.

Mrs. B. promptly recovered from the operation and promptly recovered her normal health. Her nervousness disappeared, and her usual cheerful and equable temperament was restored to her. Her husband's later account to me of the year which followed was encouraging, if it had not been pathetic. At any rate, the operation showed brilliantly the immediate benefit of cutting out a greatly active gland which obviously was pouring toxins into the patient's organism. Mrs. B.'s after-history, however, was stormy and instructive. Her symptoms of hyperthyroidism gradually returned after a year and became more settled and more pronounced than before. Not only was she the victim of an intense nervousnses on this second occasion, but she developed many of the classical symptoms of Graves' disease; her eyes became prominent, with the usual associated lid symptoms; the remaining lobes of the gland became enlarged to about four times their normal size; tachycardia developed, though not in an extreme degree, but her pulse came to range between 100 and 110; she became the victim of dyspnea and palpitation, while her digestive disturbances were poignant, — pain after food, eructations and constant diarrhea, — associated also with rapid emaciation. Such was her condition when she consulted me, some fourteen months after the first operation.

I endeavored for some two months to relieve her symptoms and to build her up by the use of hydrobromate of quinin, but at the end of eight weeks she was but little improved, and the outlook began to appear very serious. Meantime, her husband and her physician, who had performed the first operation, both urged me strongly to proceed with a second operation. It was evident to all concerned that the failure of the first operation to effect a cure was due to the incompleteness of the work. It was said, with apparent justice, that much more of the affected gland should have been removed. At this time, that is to say, immediately before my own operation, which I undertook with some hesitation, the patient, while extremely ill in the thyroid sense, seemed to be an excellent surgical risk. She had herself well in hand and exhibited little of the terror and perturbation which these people usually show when an operation is anticipated; indeed, it did not appear to me that my usual course of psychic treatment was indicated; the patient was so perfectly familiar with her coming ordeal, and so keenly intelligent about preparing for it, that I thought it best to consult her about the day and the circumstances of the operation.

On the appointed day she walked to the operating room herself to take her anesthetic, and appeared reasonably placid. Her pulse was 106, of fair quality, but slightly intermittent. There were no evidences of degenerative changes in the heart or nervous system, though a slight, hemic, mitral murmur was obvious; the heart, however, was not enlarged. I anesthetized this patient with gas and oxygen with the greatest immediate success. The combination of these agents is usually peculiarly effective in cases of Graves' disease. At the same time, in order to block, so far as possible, the effects of hyperthyroidism, I followed the suggestion of Crile and infiltrated the skin about the tumor thoroughly with a 1% cocaine solution. I found the operation of thyroidectomy in this case unusually difficult. The previous operation had had the common effect of filling the operative field with extensive and dense scar tissue, through which there was an abundant blood supply. The dissection was most painstaking and bloody, though the total amount of hemorrhage or of blood lost was inconsiderable, I am convinced. At one time I counted 47 hemostatic forceps in the field of operation, and I am sure there must have been twice that number before the operation was completed. All this, of course, shows the difficulty of the operation and its length. The thyroid lobes seemed everywhere closely adherent to the surrounding structures. I found the stump of the old left lobe which had been removed, and proceeding thence I took out the somewhat enlarged pyramidal lobe and about half of the enlarged right lobe. I assured myself by this method — that is, by slicing laterally the right lobe — that the parathyroid glandules were

not disturbed. To the same end, the blood vessels were seized and controlled within the substance of the gland itself. The operation occupied about thirty-five minutes and was extremely tedious; the patient bore it well, however; her pulse rose but little, and while the stitches were being put in, it was counted at 112. While she was recovering from the anesthetic, that is, fifteen minutes later, her pulse had sunk to 100, and all promised well.

Every reasonable operative precaution had been taken to avoid increasing the hyperthyroidism. In spite of the dense adhesions about the gland, that organ had been handled very little, while after the operation abundant drainage was provided. Even so, one recalls with interest Crile's assertion, based on numerous investigations and experiments, that the escape of thyroid secretion during the operation has little or nothing to do with post-operative hyperthyroidism.

Trouble began immediately after our patient was put to bed. She was the victim of an intense and prolonged nausea, vomiting frequently and painfully for twelve hours. She awoke to consciousness in a state of excessive irritability, throwing herself about the bed, demanding to be taken up, crying out for the nurse every two or three minutes, continually asking for ease from her discomfort, a discomfort which she failed to describe; her apprehension became painful and extreme, her agitation seemed almost maniacal, and her former tranquillity was so far abolished that she complained bitterly and continually of her attendants and of the nature of her treatment. She bewailed the fact that she had submitted to a second operation, and assured us continually that she was about to die. At the end of twelve hours the reasonably slow and steady pulse had risen irregularly to 130 and 140, the heart action became embarrassed, intermittent and irregular; a rapid cardiac dilatation supervened; the patient was bathed in sweat; her exophthalmos became exaggerated in appearance and her misery became almost indescribable. In other words, here was presented a picture of extreme and grave thyroid poisoning, such a picture as one sees in the most advanced cases of Graves' disease immediately before death; indeed, death was imminent in the case of this unfortunate patient. I attempted in every way to relieve her misery by the use of appropriate drugs, but the rapid deterioration of her heart seemed to render them ineffective; opium alone gave her some slight comfort.

The situation was such as we used commonly to encounter after operating for Graves' disease two or three years ago, before the present effective technic had been devised.

The patient sank rapidly under her accumulated sufferings and died some thirty-six hours after the operation. She died of acute hyperthyroidism.

The case in its development and in its early features was conspicuously atypical, and although during that interval between the first and second operations characteristic symptoms accumulated, so that the case became almost classical in its appearance, still the condition at no time was regarded as serious. One cannot but ask oneself what would have happened had no operation been done. In spite of the futility of this question, one cannot but feel that had no second operation been done, the patient must have continued on the edge of a volcano, and that at any time, almost, some slightest excitement or stimulus might have thrown her into a state of advanced hyperthyroidism from which she could not have been rescued. Looking back at my own relation to her illness, that is, during the last two months of her life, and at the course followed, I believe now that I should not have dallied with drugs, but should have followed the example of her first surgeon and operated immediately after she consulted me.

The two cases which I have related, eventually and pathologically, were cases of frank, acute Graves' disease. There was no evidence in the thyroid lobes removed that any retrograde changes had as yet begun in those organs. It is to such retrograde changes, with their associated symptoms, leading in the last event to the antipodes of Graves' disease, to an actual myxedema, that the physician must often look for spontaneous cure of hyperthyroidism. Neither in the case of Mrs. S. or of Mrs. B. were such changes evident.

These two cases, little as they resemble each other, illustrate that great class which should be treated by early thyroidectomy.

HYSTERIA — WITH AUTOPSY.*

BY WILLIAM R. WOODBURY, M.D.,
Head of Department for Nervous Diseases, Boston Dispensary;
AND
CARLISLE REED, M.D.,
Assistant Physician in Nerve Department, Boston Dispensary.

In January, 1909, a young colored girl, seventeen years old, came to the Nerve Department of the Boston Dispensary. She came reluctantly with her mother; and this is the story they brought:

At two and one-half years of age came her first sickness: she had whooping cough. For six to eight weeks she was very ill. It was nearly a year before there was full recovery. Then followed immediately measles, which was not a particularly severe illness. When she was five and one-half years old she was vaccinated. The first vaccination did not take. The second vaccination took. Up to this time the skin of her entire body was perfectly clear. A rash appeared with the vaccination and the swelling of her arm. From head to feet the entire body was covered with "white boils." These in healing left permanent white marks on her colored skin. These white spots distressed the girl greatly when she began to attend school — at six years of age. During the following two years she was taken to the Carney and Homœopathic hospitals, but she was never cured. Her body and scalp had a scaly eruption which was white, dry and did not itch. At times the eruption appeared to be gone; then it would return.

At eight years of age she had tonsillitis. She was in bed ten days. Following the tonsillitis appeared for

* Read at a clinical meeting of the staff of the Boston Dispensary, May 6, 1910.

the first time her "bladder trouble," which the mother said began "with a constant desire to pass her water." This "trouble" was continuous the next one and one-half years. At the Carney Hospital "kidney trouble" was suspected, and the doctor wanted the girl to go into the hospital. She refused, and she cried, and her mother took the girl home. From that time (eight years of age) to sixteen years of age she made no complaint of "water trouble." Menstruation began when she was fifteen years and two months old — in February.

At sixteen years of age she weighed 118 to 123 lb., and it was generally remarked how well she looked. In December of her sixteenth year she went to visit her grandmother, who lived in a nearby city. The visit lasted one week. On her return Lucinda began not to seem well. She complained of being tired, and her "water trouble" became constant. As soon as the bladder was relieved the desire to urinate returned. She said, "I always felt as though there was a drop more that I could not get rid of; it was always irritating." Her disposition began to undergo a complete change. She grew more irritable; she was peevish; she was easily annoyed; and she became less unselfish. She began to lose in weight, and from that time on her weight steadily fell away.

The physical examination discovered a fairly well-developed but poorly nourished body. The skin, save that of the face, carried a general psoriasis. Where the psoriasis had healed and the scales had come off were white scars which showed prominently on the dark skin. Above the pubes was a slight tenderness. The heart and lungs were normal. The girl refused to answer questions, but when pressed she would break her silence only with a whining, "Mamma, you tell him; mamma, you tell him." During the time we were getting her history and making the physical examination she insisted on going to the toilet three times. Her mind seemed centered on her bladder; she would continually say, "My bladder," — nothing could get her attention away from it. She depended absolutely and always on her mother to do everything for her. The girl demanded constant service night and day. She insisted on keeping her mother with her all the time; she compelled her mother to sleep with her.

If any one was about at meal times she refused flatly to eat. A member of the family said, "Lucinda liked to eat, but she hated to have any one know it." When in bed she would eat under the sheet so as not to be seen eating. Analysis of her urine revealed nothing to be remarked.

During the year previous to coming to the Dispensary the girl was under the care of a number of physicians. At one time she was in the Vincent Hospital for a period of two or three months. While there she urinated at intervals of from every fifteen minutes to every three hours. Some kind of treatment was given for the bladder, but nothing was discovered, no relief came. After that she became a patient at the Emmanuel Church Clinic.

From January to Aug. 4, 1909, we kept in closest touch with the patient at the clinic and in her home. She came with her mother to the Nerve Room at regular and frequent intervals, but she always came most reluctantly, — under vigorous protest, — and she showed much vigor and no little determination in her conduct towards us. Our Medical Social Service visitor saw the girl, her mother and the family frequently in their home. We all endeavored to stimulate the girl to try to do something for herself, to want to do for herself. Our efforts singly and combined met with no success. When her mother returned to her own bed and locked her door, Lucinda would spend the entire night between going to the bath room and sitting crying at the head of the stairs opposite her mother's bedroom door. The girl would eat only after much urging, and then she ate very little. Naturally she grew steadily weaker, and was losing in weight, but her endurance held good. "Lucinda says she will jump out of the window" was the message which came one day from her excited mother. Upon the information that the window was in the second story, the mother was told to tell Lucinda that she might jump if she wanted to. This closed the window incident. The girl made no more mention of the subject.

On the 17th of April she was taken into the Milton Convalescent Home. She was to stay there three weeks. The third day after being admitted we were requested to have her removed at once. She cried and raised such a rumpus generally that the interests of the other patients demanded her speedy departure.

Dr. Edgar Garceau saw the patient at his office, by appointment, and gave her a painstakingly careful examination. His report was:

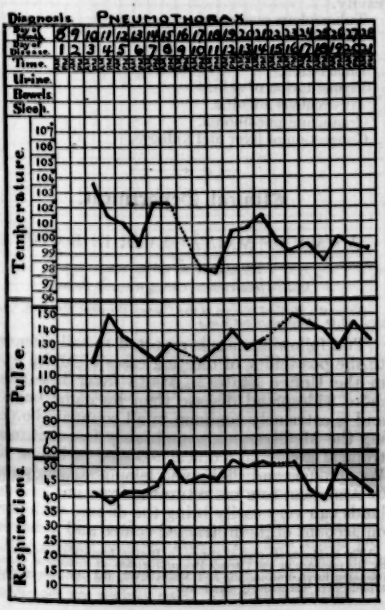
PLEASE FILL OUT THIS CARD AND RETURN TO
SOCIAL SERVICE DEPARTMENT
NO. { *Nerve Room* / *2456* BOSTON DISPENSARY
COR. BENNET AND ASH STREETS

FOUND *Extreme emaciation, anemia. Contracted bladder. Hyperemia of trigone and vesical neck. Hyperemia of the kidneys (calcic oxalate and diminish amount). There was so much emaciation that I suspect deep-seated disease (adrenal tumor?).*

RECOMMENDED *Advise against bladder treatment now. Better rest a while and return for examination later.*

DATE *May 11, 1909.* (SIGNATURE) EDGAR GARCEAU.

The girl's condition was not improving; she was steadily becoming weaker. Nothing would stimulate her into any effort; she continued, and strenuously, her tyranny over the family. In July she was taken to Nova Scotia to visit some family friends. Her mother remained at home — she was compelled to help meet the family living expenses. Lucinda knew this, yet she moaned and so carried on that in a few days an urgent telegram came to her mother to come at once and take the girl home; she was in bad condition. The girl had refused all food for the entire ten days. She had taken only two quarts of milk and a few caramels, and she sat throughout those ten days in one position, her favorite one, with her right leg doubled up under her.



On her return she went to bed and there on Aug. 4 she was seen at her home. Her emaciation was much more advanced; and she complained of a numbness and inability to move her right foot — a pressure paralysis resulting from her ten days' sitting on that leg. Physical examination revealed nothing else. It was necessary to force her to take food. She would eat candy and cookies, but nothing else. Her silence was still sphinx-like. During the remainder of August, September and up to Oct. 8 the usual condition continued, but naturally the emaciation and physical weakness were advancing. She was a mere skeleton. On Sept. 28 her grandmother died. The mother left the patient — who had demanded her constant attendance day and night — and she made no remonstrance against the mother going to the nearby city where the grandmother had died. The grandmother's death seemed to bring the girl back into a state of reasonableness, and she ate willingly; she was less tyrannical.

At four o'clock of the afternoon of Oct. 8, the girl was seized with a violent attack of coughing which lasted until nine o'clock in the evening. She said there was something in her throat which she could not get

up. Suddenly she cried out and fell out of the chair to the floor, but she complained in no way of being hurt. An examination of the throat discovered nothing; but there was found a left pneumothorax, with the heart displaced to the right. The next day there was a high pulse-rate and temperature, and the girl was weak and had labored and rapid breathing. She was pale, extremely emaciated and had a constant, dry cough.

On Oct. 10, the left chest was slightly larger than the right, and tympanitic on percussion. The pulse was 120, small and weak; respirations were 40 and labored; and the temperature was 103.5. On the left side of the chest the breath sounds could not be heard: they were replaced by a peculiar metallic sound like the ringing noise made by striking on an empty rain-barrel or hogshead. On the right side the breath sounds were intensified, harsh and hurried. The heart sounds were clear but weak, and dullness or percussion was found two finger breadths to the right of the sternum. The three weeks that followed were relatively uneventful save that all the symptoms previous to the pneumothorax had disappeared, and the girl became her old rational self. She ate well, and without any urging; her bladder trouble was forgotten; she talked and asked to have her friends come and see her; and she replied to questions asked her. The right lung became slightly edematous on the seventh day, but in a day or two it had practically cleared up. On the fifteenth day the edematous condition reappeared and disappeared as before. On but one occasion (the twelfth day) during this time did she complain of the bladder. She felt some pain and retained her urine. Four ounces of urine were drawn with a catheter, and no further disturbances followed. Bed sores developed on the sacrum on the nineteenth day, and these never wholly healed. The last three days fluid appeared in the left chest.

Lucinda died following a sinking spell, Oct. 27, — the twenty-first day of the pneumothorax. Nine hours after death the autopsy was made by Dr. A. W. Hunter, of the Boston City Hospital. His report is:

AUTOPSY.

Peritoneal cavity. — Surfaces are normally smooth, with a slight increase of fluid in the cavity. This fluid is clear, limpid and estimated at 100 ccm. The liver extends 10 cm. below the costal border in the median line and 8.5 cm. in the right midclavicular line. Diaphragm, right sixth rib; the inferior surface is evident in the median line. It has a convexity downward and it is palpable along the costal margin to the level of the eighth rib, where it recedes backward along the eighth and ninth ribs. Throughout its course the convexity is evident downward. The large intestine is moderately distended with gas. Mesenteric lymph nodes are visible, but not enlarged. The appendix lies retrocecal, and is 6 cm. long, with an old, thin, fibrous band stretching across its mid-portion, but apparently is not remarkable.

Pleural cavities. — On percussion over the left side of the thorax there is a hyperresonance of tympany. After reflexion of the skin on the anterior thoracic wall a small amount of water was poured between the skin and the thoracic wall, all bubbles removed and a puncture made into the left thoracic cavity below the water line. Through this opening a continuous series of bubbles escaped. On removal of the sternum the left parietal pleura is of a gray color and studded with minute, raised, gray papules.

Right cavity. — A few firm, gray adhesions are present on the posterior and apical parts of the visceral pleura. In the cavity there are estimated to be 300 or more cubic centimeters of yellowish, clear, limpid fluid. The interlobar cleft between the upper and middle lobes is obliterated by adhesions, and slightly between the middle and inferior lobes in the axillary line.

Left cavity. — The heart occupies the median line. The left lung is contracted and occupies a small area along side of the vertebral column. The pleural cavity is empty except for 300 or 400 ccm. (estimated) of yellowish, slightly turbid, fluid. The upper half of the parietal pleura in the axillary and posterior portions is injected and covered with a thin layer of friable, gray, fibrinous adhesions. Similar scattered areas along the parietal wall are evident. On the visceral surface the pleura is thickened and superimposed; on this gray, thickened pleura is a layer of gray, friable, elastic exudate. The interlobar cleft is obliterated. At the inferior posterior portion of the upper lobe there is a firm, gray, fibrous band binding the lung to the parietal wall; this band is 1 cm. in thickness. Immediately below it is a circumscribed round hole 1 cm. in diameter which communicates with a cavity within the lung. The entire lung is bound posteriorly along the median line to the posterior parietal wall and the vertebral column. The left lung measures 11 cm. in its vertical diameter and 13 cm. in its antero-posterior diameter.

Pericardial cavity. — The surfaces are normally smooth, moist and glistening. Cavity contains 50 ccm. of pale, limpid fluid. In the unopened pericardial sac the heart lies 4 cm. to the left of the median line at the fourth space and 2 cm. to the left at the sixth rib, while it reaches 7 cm. to the right of the median line at the fourth space.

Heart. — Appears small. Scattered over the epicardial surface, particularly at the right auricle and the left ventricle, there are circumscribed, gray, opaque, macular areas. On section the musculature is brownish colored and of fair consistence. The endocardium is

smooth, as are also the valves. The coronaries are not remarkable.

Measurements: Tricuspid valve, 10.3 cm.; pulmonary valve, 6.3 cm.; mitral valve, 8 cm.; aortic valve, 5 cm.; left ventricle, 1.2 cm.; right ventricle, 4 mm.

Right lung. — Upper lobe: The apex and posterior margin of the right lung are of a mottled, grayish-red color, crepitant throughout, on section very moist, with some pitting on pressure. The anterior half of the upper lobe is firm, hepatized, pinkish in color, on section dry and semi-gelatinous in appearance; it is non-crepitant and has a finely granular surface throughout. Toward the posterior margin of this area there are large, soft, rather dry, cheesy-looking, circumscribed areas .5 to 1 cm. in diameter. The posterior margin of this area also has scattered areas as afore-mentioned, surrounded by crepitant, moist lung tissue.

Left lung. — Size is much diminished. The pleura is covered with adhesions as afore-mentioned. Lower lobe: Diaphragmatic surface feels firm, hepatized and gradually fuses in its upper part with mottled, grayish, crepitant lung tissue. The upper lobe at its inferior posterior surface has an opening afore-mentioned. On dissection of the primary bronchi of the left lung there is evident an injected mucosa with five circumscribed, raised, minute nodules on its surface. Deeper in the lung substance the bronchioles are more injected, and one area has a continuous studded area with gray, minute papules. This bronchiole leads into a cavity which communicates with the afore-mentioned hole. This cavity is approximately 5 cm. in diameter vertically and 3 to 4 cm. in its antero-posterior diameter. Its walls have a gray, necrotic, firm appearance, as has also the pleural opening. In the upper third of the upper lobe there is a circumscribed, protruding, nodular mass 6 cm. in diameter, of a mottled, grayish-red color on the pleural surface and firm to palpation. On section it has a soft, slightly moist, gray, granular appearance surrounded by a deep red, very moist, crepitant lung substance. The peribronchial lymph nodes are palpable, but on section not remarkable.

Spleen. — Is apparently of normal size. On section it has a mottled, deep red color. Pulp is scant; trabeculæ prominent.

Gastro-intestinal tract. — Aside from the slight distention of the large intestine, it is not remarkable.

Pancreas. — Is well-shaped and negative.

Liver. — Weight estimated at 1,200 to 1,500 gm. The capsule is smooth; on section it has a mottled, yellowish-red color which is uniform throughout. The small sinusoids appear somewhat prominent and filled with pus. Gall bladder is moderately distended with green bile.

Kidneys. — Weight apparently of normal size. Slight fetal lobulations persisting. The capsule is thin and non-adherent, leaving a smooth surface when stripped. On section the cortex and pyramids have a mottled, dark red color. Considerable blood oozes on to the cut surface, particularly in the pyramids. The cortex is of normal thickness; otherwise the kidneys are not remarkable.

Adrenals. — Negative.

Bladder. — Is moderately distended with urine. The mucosa is smooth. Beneath the mucosa there are numerous mottled, dark red areas which on section do not appear to involve the muscular coat. They are most evident on the inferior surface of the bladder.

Genital organs. — The vagina is negative. Cervix is conical and patent. The uterus is small and firm; the mucosa of deeper red color. The tubes and ovaries are apparently negative.

Aorta. — Is smooth, elastic and of a pale yellow color.

Thoracic duct. — Is defined but not remarkable.

Head. — Not done.

MICROSCOPICAL EXAMINATION.

Heart. — Negative.

Lung. — Much fibrin in alveoli; endothelial leucocytes; areas of caseation. Small areas of apparent connective tissue growth within the alveoli. Diagnosis: Tuberculous pneumonia; organizing pneumonia.

Pleura. — Areas of tuberculous nodules showing giant cells. Other part shows necrosis, fibrin, giant cells and connective tissue increase.

Spleen. — Negative.

Stomach. — Negative.

Intestine. — Mucous cell débris and bacteria on gut mucous membrane.

Pancreas. — Negative.

Liver. — Congested.

Kidney. — Congested.

Adrenal. — Negative.

Lymph node (peribronchial) shows areas of tuberculous necrosis and giant cells.

Uterus. — Negative.

Gall bladder. — Desquamation of cells.

Bladder. — Submucosal edema, congestion and a small submucosal hemorrhage.

Aorta. — Discrete nodules of intimal proliferation and thickening.

ANATOMICAL DIAGNOSES.

Pneumothorax.
Acute pleurisy with effusion. } Tuberculous.
Chronic tuberculous pleuritis. }
Hydrothorax.
Hydropericardium (slight).
Hydroperitoneum.
Chronic abscess of lung with rupture into the pleural cavity.
Tuberculous pneumonia.
Tuberculous bronchitis.
Atelectasis of lung.
Emaciation.
Pigmentation of skin.
Tuberculous adenitis.
Organizing pneumonia.
Congestion of liver and kidneys.

Clinical Department.

A CASE OF MALTA FEVER IN BOSTON.

BY HAROLD H. SMITH, M.D.,
Medical House Officer, Carney Hospital, Boston.

(From the Medical Service of the Carney Hospital, Henry A. Christian, M.D., Physician-in-Chief.)

THE following case is reported to call attention to the possibility of meeting cases of Malta fever in the United States.[1] Malta faver is a much more widespread disease than its name implies, and is extremely common in all countries bordering the Mediterranean, and fairly frequent in all tropical and semi-tropical regions, including the West Indies and Philippine Islands. Immigrants or American tourists returning from any of these lands can very easily bring the disease with them on account of its protracted course and numerous

[1] The incidence of tropical diseases in Boston hospitals is emphasized by the presence at the Carney Hospital within six months of cases of relapsing fever, uncinariasis and Malta fever, and one case in which typhus fever was strongly simulated.

remissions. Such cases undoubtedly occur here with considerable frequency, although they are rarely recognized.

Therefore, the possibility of Malta fever should be considered in every obscure case of continued or remittent fever occurring in a person lately returned from any of the above-mentioned countries, if the physical signs are practically negative, except for enlarged spleen; if the leucocyte count is persistently low, and if the blood serum fails to agglutinate typhoid and paratyphoid organisms. In such a case the diagnosis can easily be made or ruled out by determining the agglutinating power of the patient's serum toward the *micrococcus melitensis*. Positive blood cultures have been obtained by some observers in a high percentage of cases and furnish even better diagnostic evidence than agglutination, but a negative culture does not rule out the diagnosis.

Patient is a male Italian, thirty-nine years of age, married, a shoemaker. He had always lived near Palermo, in Sicily, and came to the Carney Hospital directly from the United States Immigration Bureau, May 9, 1910. Patient speaks no English and very little in the way of history could be obtained except that he had been sick with fever for four days and had had three slight chills.

Physical examination shows a well-developed and well-nourished man lying comfortably in bed, breathing somewhat rapidly.

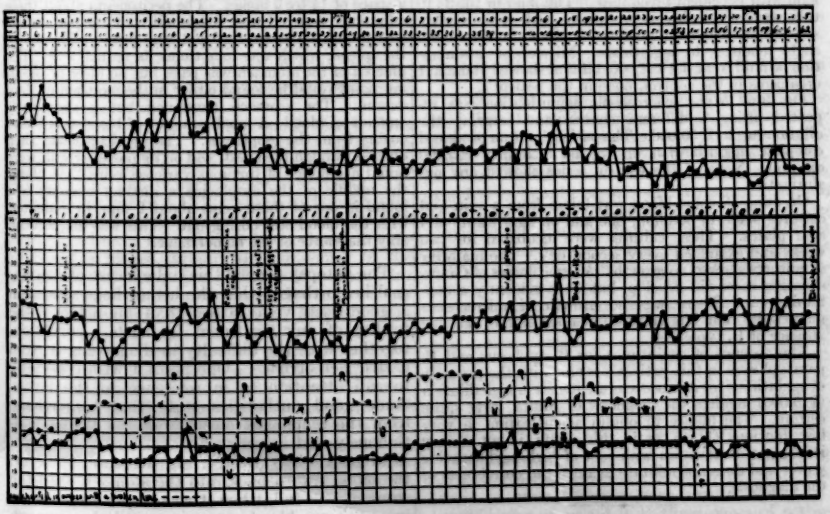
Glands show no general enlargement.

Neck: There is no rigidity. There is visible carotid pulsation on both sides.

Skin is hot and dry, shows no rash and no scars.

Chest: Well formed, symmetrical, expands equally on both sides.

Lungs: Resonance is normal in front; behind there is slight dullness over the left base. Breath sounds are somewhat diminished in intensity over both bases behind, but are normal elsewhere. Tactile fremitus and voice sounds are everywhere normal. There are many fine moist râles and a few high-pitched musical râles over both bases behind, more on the left. Occasional fine moist râles are present on both sides in front.



Heart: The apex impulse is seen and felt in the fifth space, 3½ inches to the left of the mid-sternal line. The left border of dullness is 4 inches from the mid-sternal line; right border at the right sternal margin; upper border at the top of the third rib. Heart's action is regular, sounds clear and loud. No murmurs.

Radial arteries show slight thickening. Pulses are equal, synchronous, regular, fair volume and normal tension.

Abdomen: Level, soft, no tenderness. No masses felt. Liver dullness extends from the fifth intercostal space on the right to the costal margin; its edge is palpable. Spleen is markedly enlarged, its edge being easily palpable two fingers' breadth below the costal margin. The edge is sharp and the organ seems firm.

Reflexes: Knee jerks are present and equal. There is no Kernig or Babinski sign. No ankle clonus.

Extremities: Negative.

Pupils are equal, regular and react promptly to light and with accommodation. External ocular muscles are normal.

Mouth: The teeth are neglected and carious and there is marked pyorrhea alveolaris. The tongue protrudes in the median line, is covered by a moist white coat and shows a fine tremor. The lips and oral mucous membranes are slightly pale. Pharynx is normal.

Genitals: Negative.

Blood: Hemoglobin, 85%. Leucocyte count, 4,000. Stained smear is not remarkable. There are no malarial plasmodia in either fresh or stained specimens. Serum does not agglutinate *B. typhosus*.

Stool: A very few ova of ascaris lumbricoides and trichuris trichiuris.

Sputum shows no tubercle bacilli.

The case appeared to be a mild typhoid, but malaria and tuberculosis were strongly considered. The patient had no chills while in the hospital, and repeated blood examinations failed to show any plasmodia. Sputum was very scanty and never showed tubercle bacilli.

The subsequent course is best shown by the accompanying chart. The patient complained of practically no pain at any time. There was moderate constipation throughout. The pulmonary signs persisted for nearly two weeks and then gradually cleared up except for a small area below the right nipple. Over this area there were persistent fine moist râles. At one time there was heard a slight friction sound in the right axilla; this disappeared in a few days. The spleen became progressively smaller, but was still palpable when the patient left the hospital. The leucocyte count never went higher than 6,000. The blood serum failed to agglutinate *B. typhosus*. A single agglutination test with paratyphoid bacilli was negative.

Suspecting Malta fever, on May 24 cultures were made from a catheter specimen of urine. These cultures were negative except for a few colonies of Gram-positive cocci, apparently staphylococcus albus.

On June 1 a microscopic agglutination test was tried, using the patient's serum and a fresh bouillon culture of the micrococcus melitensis. The 1:10 preparation showed no clumping after one hour. The 1:50 preparation showed marked clumping at the end of half an hour. On the following day a macroscopic agglutination test was performed, using bouillon cultures and patient's serum in dilutions 1:10, 1:100, 1:500, 1:1,000. A control series of similar dilutions of normal serum was also prepared. At the end of fifteen hours the 1:100, 1:500, 1:1,000 preparations of patient's serum showed clear fluid with flocculent precipitate. The fluid in the 1:10 tube was turbid with no precipitate. All of the control series were turbid, although the 1:10 dilution showed a slight tendency to agglutinate. Microscopic examination of fluid from the 1:1,000 dilution showed abundant organisms in the control, none in the patient's.

On June 5 the macroscopic agglutination was repeated, using a different control and carrying the dilutions up to 1:50,000. The patient's serum produced complete agglutination up to and including 1:5,000 dilution. None of the control series showed any agglutination.

On June 18 some blood was taken from a vein and cultures made in bouillon, bile and on agar slants and agar plates.[1] These cultures were incubated for two weeks and examined every second day. The majority of cultures showed no growth. A few colonies of Gram-negative cocci did develop, but were evidently a contamination. There was no growth of micrococcus melitensis. The bile culture remained sterile, showing absence of B. typhosus.

The absence of agglutinins for B. typhosus and B. paratyphosus in this patient's serum with the presence of agglutinins for micrococcus melitensis in high dilution (1:5,000) renders the diagnosis of Malta fever quite certain. The failure to obtain agglutination in very low dilutions (1:10), as in this serum, is not a very infrequent observation with sera of high agglutinating power and does not militate against the correctness of the diagnosis.

ESOPHAGEAL HEMORRHAGE.

BY C. C. NICOLA, M.D.

THE following case is reported on account of its unusual character and to add to the statistics of this class of cases.

[1] For assistance in making and studying the blood cultures, I wish to acknowledge my indebtedness to Daniel J. Hurley, M.D., of the Pathological Department of the Boston City Hospital.

The patient, Mr. E. S., was brought into the Attleboro Sanitarium Hospital on the morning of Nov. 20, 1909, with a history of severe and persistent hematemesis. Patient was married, thirty-eight years old, an employee in a jewelry factory. He was referred to the hospital by Drs. Holman and Kent, from whom and from the patient's wife the following history was obtained:

Patient had always been generally well, except for occasional indigestion. Last night he went with his wife to the theater, apparently in perfect health. At 9.30 he complained of a feeling of fullness and warmth in the stomach. On reaching home, he vomited a large quantity of blood and food. A physician was called and the vomiting recurred. The attending physicians estimated that at least three quarts of blood were vomited. By morning he was practically pulseless, but was revived somewhat and brought to the hospital in an automobile. Soon after arriving, at 9.30 A.M., he vomited 1½ pints more of dark blood. He was given ¼ gr. morphine, with ice-bag to epigastrium and heat to legs. A saline enema was administered. His pulse was 130 and very weak; mind clear and active. The vomiting stopped and the patient seemed very cheerful during the afternoon. About 5 P.M. he suddenly began to breathe irregularly, and in ten minutes was dead.

An examination of the early vomitus showed undigested food, including good-sized pieces of beef tongue with hard rind which had been swallowed without chewing. A hurried autopsy was held just before the body was removed from the hospital. The stomach was found distended with gas and the posterior surface of the pyloric end was firmly adherent to the liver over a space of 1½ by 3 inches. The peritoneum about these adhesions was red and congested, but no perforation was found. The cardiac end was firmly adherent to the spleen, which was four times its normal size. The mucosa of the stomach was pale, but no ulcer or bleeding point could be found either in the stomach or duodenum. The stomach contained but a very little amount of blood. A small amount of blood was found oozing from the esophagus. The esophagus was then opened through the chest, and on its posterior wall were found a number of tortuous varicose veins. At about the middle of the esophagus a distinct opening was found in one of these veins about 2 mm. in diameter, with the blood still oozing out. This was unquestionably the source of the hemorrhage.

The autopsy proved this to be a case of esophageal hemorrhage; that the hemorrhage was from a good-sized vein rather than an artery; the futility of any treatment for such a condition, together with the difficulty in diagnosing it from gastric hemorrhage. One point I wish especially to call attention to in reference to the latter. Some good authorities state that hemorrhage from the esophagus oozes from the throat continuously and is not vomited from the stomach, as in gastric hemorrhage. In this case, however, the blood flowed back into the stomach until the stomach was full, when it was emptied by vomiting, no more blood appearing until the stomach was filled again.

It is also remarkable that this patient should have had no greater disturbances of digestion preceding the hemorrhage in view of the inflammation which he must previously have had in order to produce the adhesions which were found between the stomach and liver and spleen.

Medical Progress.

RECENT PROGRESS IN PHYSIOLOGICAL CHEMISTRY.

BY J. BERGEN OGDEN, M.D., NEW YORK CITY.

TITRATION OF URINARY ACIDITY.

O. SPINDLER [1] has studied this subject and has reported that acidimetric titrations in presence of NH_4 salts do not give exact results unless allowance is made for the retardation of the end reaction caused by the dissociation of these salts. This effect depends upon the degree of dissociation, and may be minimized by the addition of a neutral and indifferent salt, such as NaCl. These principles are especially important in application to urine, the apparent acidity of which is strongly influenced by variations in NH_3. The exact acidity of urine cannot be titrated unless the content of NH_3 is known, and vice versa. Method: Place 20 ccm. urine in a 100-ccm. flask; add 20 ccm. $\frac{N}{10}$ NaOH, 10 ccm. of a 10% solution of barium chloride, mix, dilute to 100 ccm., and filter. To 50 ccm. of the filtrate add 10 ccm. $\frac{N}{10}$ H_2SO_4, three drops of phenolphthalein solution, and titrate the acidity with $\frac{N}{10}$ NaOH. To determine NH_3, add excess of CH_2O and continue the titration with NaOH.

A CLINICAL METHOD FOR THE QUANTITATIVE ESTIMATION OF URIC ACID IN BLOOD SERUM.

P. Roethlisberger [2] has investigated this subject and reports as follows:

The test is carried out in a room that is dark or contains little light. A red light or an electric light is used, and a strip of silver nitrate paper is placed in a tightly closed glass or porcelain box. One ccm. or less of a 15% sodium carbonate solution is placed on the reagent paper and the box kept closed until it is all absorbed. A single drop of blood is placed directly on the center of the moist spot of the paper. The box is closed for two minutes and then the paper is removed and washed in the dark in pure water. After ten minutes the paper is placed in a solution of one part NH_3 to two or three parts of distilled water for five minutes. The paper is again washed in water. After standing in the water bath for several hours away from the light the paper is dried and examined for a stain. When wet it shows a gray spot. When uric acid is present, the carbonated paper shows a yellow spot which changes with increasing concentrations of uric acid to brown, red and dark brown. In cattle, sheep and horse blood, also in ox, pig, rabbit and dog blood, no uric acid was found; 0.008% uric acid was found in birds' blood. Varying amounts of uric acid were found in the blood of a five-year-old child fed on a meat-free diet; in healthy cases 0.001–0.004% were found. In cases of chronic nephritis and nervous disorders, 0.008–0.012% of uric acid were found. The possibilities of the influence of other reducing agents on the test are noted. With this method from 1-1,000th to 1-2,000th part of uric acid is detected, and the results calculated to 100 ccm. of serum are accurate to 1 to 2 mgm. Illustrations of the test using cattle blood serum and amounts of uric acid from 0 to 0.012% are given.

IRON OF THE URINE.

Urines of a number of animals were all found by O. Walter [3] to contain measurable amounts of iron. It is present in colloidal condition, and urine can be dialyzed twenty-four hours without loss of iron. The latter is present in two forms, a "loosely combined" form, from which it is precipitated by boiling with $(NH_4)_2S$, and a "closely bound" form which can be determined only in the ash. The loosely combined iron is determined by neutralising the urine (entire twenty-four-hour portion) with NH_3, adding $(NH_4)_2S$, and concentrating on the water bath to one third its volume. The solution is filtered and the precipitate dissolved in dilute H_2SO_4. The iron is oxidized to ferric condition by boiling with 2 ccm. H_2O_2 solution and titrated with KI and $\frac{N}{10}$ $Na_2S_2O_3$. To determine the closely bound iron the urine is first dialyzed twenty-four hours, then concentrated to dryness with 30 ccm. concentrated HNO_3. The residue is charred on a sand bath and ashed in crucibles. The ash is dissolved in 10% HCl, boiled three quarters of an hour with 2 ccm. 3% H_2O_2, treated with 2 gm. KI, and titrated with $\frac{N}{10}$ $Na_2S_2O_3$. A correction of 0.32 mgm. iron was made for the iodine freed by the undecomposed H_2O_2. The daily excretion of iron for a man, or a 20 kgm. dog, is about 1 mgm. In herbivorous animals (rabbit, ox, sheep, goat) a considerable portion of the Fe excreted is loosely combined. In normal human urine none can be detected in this form. Cases of pernicious anemia, diabetes and polycythemia rubra excreted about twice the normal amount of iron, a portion being loosely combined. Continued administration of medicinal blood-Fe preparations to men or dogs increases the Fe excretion. Subcutaneous injection of officinal Fe preparations causes a quick increase in Fe excretion, usually accompanied by injury to the renal epithelium.

THE OCCURRENCE OF A PIGMENT SIMILAR TO UROROSEIN IN CERTAIN PATHOLOGICAL URINES.

Nephrorosein, a pigment similar in many of its properties to urorosein, is often found in the urines of convalescents from scarlet fever. V. Arnold [4] also observed it in three cases of orthostatic albuminuria, once in a case of tuberculosis and once in a case of hematoporphyrinuria following sulphonal poisoning. In properties the pigment may be differentiated from urorosein by the fact that the color does not fade so quickly after addition of the acid, and by the absorption spectrum of an amyl alcohol extract of the urine after

addition of one-third volume of concentrated HCl and one drop of 1% $NaNO_2$ (or concentrated HNO_3 alone may be employed). Urorosein gives an absorption band between D and E, while nephrorosein shows a broad band between E and F (λ517–500).

THE OCCURRENCE AND SIGNIFICANCE OF ALLANTOIN IN HUMAN URINE.

Alfred Schittenhelm and Karl Wiener [5] followed the method of Wiechowski and found allantoin in human urine, confirming Wiechowski's results. The quantity found was very small (0.02 gr. from 8 liters of urine) or was frequently impossible of isolation. The significance of allantoin in human urine is obscure. Feeding with uric acid was not found to increase the quantity of allantoin eliminated. Hence allantoin in the human being is probably not an end product of uric acid metabolism. When allantoin is fed, about 30% is recovered in the urine.

THE DETECTION OF TRYPSINOGEN AND TRYPSIN IN URINE.

E. Schoenborn [6] conducted experiments on human, pig and dog urine. Both heated and unheated samples of urine were used. Kinase and enterokinase were sometimes used. The urine was tested after hunger, also after feeding meat. When kinase from sick dogs was used, no activating action was noted. The author concludes from his experiments that active trypsin is seldom present in normal dog's urine and, when present, the amount is very small. Trypsinogen is frequently present in dog's urine and can be converted into active trypsin by means of kinase. Trypsinogen is regularly obtained in large amounts after feeding a meat diet; after a mixed diet the amount obtained is often very small. The amount of trypsinogen on a meat diet corresponds approximately to that of a solution of 0.02 gm. of Grübler's trypsin per 100 ccm. of urine. The urine of hungry dogs often contains the same amount, and after a long-continued period of hunger, during the last days, in addition to trypsinogen, active trypsin is present in appreciable amounts. After the addition of kinase, the tryptic action of this urine was noticeably increased. Moreover, in the urine of hunger a substance was frequently found which was not rendered inactive by heating and was capable of considerably increasing the action of the active trypsin. In many human pathological urines a strong antitryptic action could be detected.

THE DEPRESSOR SUBSTANCE OF DOG'S URINE AND ITS DISAPPEARANCE IN CERTAIN FORMS OF EXPERIMENTAL ACUTE NEPHRITIS.

Experiments were conducted by R. M. Pearce,[7] who found that normal dog's urine contains a depressor substance which, when urine is injected intravenously in doses of 3 ccm., has the power to cause a fall in blood pressure equal to 40–70 mm. of mercury. The exact nature of this substance was not determined. It is not destroyed at 100°, but disappears on prolonged heating. It does not dialyze readily. Alcohol precipitates it completely. The depressor substance disappears at the third to sixth day from the urine of dogs with tubular nephritis, or, if it does not disappear entirely, it is greatly diminished in amount. This disappearance or diminution was not observed in those forms of vascular nephritis due to arsenic or cantharidin. The depressor substance would appear, therefore, to be associated with normal tubule functions, a view supported by the observation that it is greatly diminished at the height of diuresis in the normal animal. Its disappearance in experimental nephritis may be taken as an indication of extensive tubular injury and its reappearance as beginning of repair. The non-elimination of this substance is accompanied in some animals by a low blood pressure, which suggests an influence due to retention of of this substance.

THE RELATION OF PTYALIN CONCENTRATION TO THE DIET AND TO THE RATE OF SALIVARY SECRETION.

No evidence could be obtained by A. J. Carlson and A. L. Crittenden [8] that in man even years of exclusion of meats and greatly increased carbohydrates in the food would appreciably increase the ptyalin concentration of the saliva. No ptyalin was found in the saliva of the dog, cat or fox. In monkeys the diastatic power of the parotid and mixed saliva appeared to be the same or less than that of man. The ptyalin concentration in the rabbits' parotid was found to be the same or slightly greater than that of man, but in the parotid and mixed saliva of the goat and horse no diastatic power could be detected. Weak acids (acetic) in the mouth were a more efficient stimulus to the secretion of the parotid than mechanical stimuli, and within limits the stronger the acid the greater the rate of secretion. The concentration of the ptyalin in the parotid saliva of the rabbit varies directly with that of the organic solids. In man the rapidly secreted parotid saliva contains more ptyalin than the slowly secreted saliva. Qualitatively, different stimuli yield no constant difference in the ptyalin concentration of the parotid saliva in man. In varying directly with the organic solids and the secretion rate the processes of ptyalin secretion appear to differ from the ferment-secreting processes in other digestive glands.

INHIBITION OF THE ACTION OF RENNET ON MILK.

The well-known fact that serum added to milk inhibits the action upon it of rennin was confirmed by Kurt Schern [9] in experiments with normal fresh beef serum. The consideration that in cows suffering from inflammation of the mammary glands serum might enter the milk and so render the milk less sensitive to rennin was borne out by experiment. It was found that to coagulate the pathological milk a larger amount of rennin was necessary than for normal milk. In one of several pathological cases observed the mixed

milk from all the udders of the same cow required 1.75 times the rennin required by normal milk. Examination of the milk of each udder showed one to require fourteen times the normal, thus locating the diseased organ. In a series of animals observed, the variations from day to day in the normal mixed milk of an individual lay between 1:1000 and 1:1400 rennin concentration in terms of the Morgenroth standard. For single udders this might be greater. The results indicate that this method of the determination of the minimum for rennet action can be used to determine pathological milk.

RESORPTION OF FATS IN THE SMALL INTESTINE.

Experiments were conducted by W. Croner[10] upon dogs provided with the Zuntz modification of the Thiry-Vella fistula. About one fifth of the intestine was included between the fistulas, the upper portion of which opened through the back of the animal, allowing liquids to be run in quantitatively, without difficulty. The lower fistula opened through the abdomen. The soap solutions or fat suspensions were run in slowly, one and one-half hours being taken to run in 30–50 ccm. of liquid. The latter ran slowly through the intestine and out the lower fistula, simulating the natural progress of the nutrient mixtures. The section of the intestine was then washed with 0.9% solution of NaCl. Recovery of unabsorbed fats was quantitative. In three animals used, the upper part of the intestine was experimented upon; in two, the part next the cecum. It was found that only the lower section of the intestine absorbs soaps. Neither bile nor gastric juice overcomes the inability of the upper parts to absorb soaps. Emulsified neutral fats are absorbed by all parts of the small intestine; most rapidly by the lower. The absorption is more rapid after the intestine has been acted upon previously by diluted HCl, pancreas, or bile. The absorption varies somewhat with the nature of the fats and their free-acid content.

A NEW DELICATE SKATOL REACTION.

T. Sasaki[11] has found that when one takes 3 ccm. of a skatol solution in a test tube and adds three drops of methyl alcohol and 3 ccm. concentrated H_2SO_4 are then run under the skatol solution, a violet-red ring forms in a short time at the boundary between the two liquids. After a few minutes the contents of the tube are carefully mixed. The entire liquid becomes violet-red. The more dilute the skatol solution, the more the violet shade predominates. The reaction permits detection of skatol in a dilution of 1:5,000,000. The ring, however, is no longer visible when the dilution has reached 1:1,000,000, the color appearing only after the liquids are mixed. The reaction fails with water suspensions because the skatol crystals touch the H_2SO_4 directly, and the entire liquid becomes brown. The reaction has an advantage over other skatol tests in being negative with indol. Tryptophane and a methyl indol also do not give the reaction. Methyl alcohol cannot be replaced by ethyl alcohol in making the test.

THE MOTHER SUBSTANCE OF GLYCOGEN.

In experiments performed upon a large number of dogs, E. Pflüger and P. Junkersdorf[12] observed the following: In a dog (5–10 kgm.) which was starved seven days, water being given and which on the mornings of the three succeeding days of continued starvation was subcutaneously injected with 1 gm. phloridzin, seven hours after the last injection the glycogen content of the liver was reduced to 0.1% and of the muscles to 0.2%. Twenty-four hours later, although no nourishment had been given, glycogen reappeared and at times in large amounts (2–3%), a fact overlooked by Mohr.[13] This increase could hardly have arisen from carbohydrates. It was found that phloridzin stimulates the production of glycogen, since the liver and muscle of dogs without phloridzin treatment contained less glycogen on the eleventh day than when treated. Dogs which had been made glycogen-free were fed for eight days on as much codfish meat (which contains but little glycogen) as they could take. The increase in glycogen content of the liver and muscle was four to five fold out of proportion to what might be contained as glycogen in the food. Dogs, however, the livers of which had been loaded with glycogen[14] by glycogen feeding, when subjected to a rich meat diet were found to lose, to a large degree, their glycogen rapidly. Glycogen-free dogs, to the diet of which easily oxidizable alcohol had been added, showed no increase in glycogen production. Therefore, the marked glycogen increase, in rich protein diet, cannot be attributed to an indirect economy of carbohydrate. Fat fed to glycogen-free dogs caused no increase, but the reverse, so that during rich protein diet the large glycogen production cannot have arisen from fat, but only from the protein.

A SIMPLE METHOD FOR THE ESTIMATION OF IODINE.

Experiments made by E. Winterstein and E. Herzfeld[15] show that 50 ccm. of solution should be placed in a 250-ccm. round-bottomed flask (which must be fitted with a ground-glass stopper through which pass two tubes, as in an ordinary wash bottle) and treated with 5 ccm. syrupy H_3PO_4 and 10–20 ccm. H_2O_2 solution. The outlet tube from the flask is joined by a ground glass connection with a small condenser, which is led into potassium iodide solution. Air is drawn through the apparatus, the contents of the glass being gradually heated to boiling. At the end of thirty minutes the iodine has all been transferred to the potassium iodide solution and is titrated with $\frac{N}{10}$ $Na_2S_2O_3$ solution. When applied to urine, it is necessary to evaporate and ignite the residue with alkali, prior to the distillation, if all the iodine is to be obtained. Figures cited indicate that the method gives very satisfactory results, which tend, however, to be somewhat low.

THE ACETIC ACID TEST FOR THE DIFFERENTIATION OF EXUDATE AND TRANSUDATE.

K. Piefer[16] who has made an investigation of exudates and transudates, finds the following tests of value. Two ccm. of the fluid removed after a puncture are treated with two drops of 5% AcOH. In the case of an exudate, a visible and more or less thick cloud appears which often is transformed into a flocculent precipitate. In the case of a transudate the cloud disappears, or after adding four or five drops of acetic acid an opalescence is produced. When a few drops of exudate are dropped into a cylinder containing 100 ccm. of H_2O and 2 drops of acetic acid, milk-white streaks develop. With a transudate the drops are divided and in certain cases a dark gray turbidity results. These tests were used in ninety-five clinical cases. Both served to distinguish transudates from exudates. Visible differences are noted in both tests when carried out with blood plasma or serum.

Reports of Societies.

THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, Held at the Planter's Hotel, St. Louis, Mo., June 6 and 7, 1910.

First Day, Monday, June 6.

The President, Dr. Julius Friedenwald, of Baltimore, in the chair.

THE PRESIDENT'S ADDRESS: RECENT EVENTS IN THE DEVELOPMENT OF GASTRO-ENTEROLOGY.

Dr. Friedenwald, in his opening address, said he could point out but a few of the many contributions that had been added to our knowledge of diseases of the stomach. After referring to Kussmaul's epoch-making work in connection with the therapeutic value of the stomach tube, it remained for Leube, in 1871, to point out the advantage of the stomach tube as a diagnostic measure and also to emphasize the fact that it was impossible to arrive at a proper conclusion concerning the nature of the gastric conditions without the use of this instrument. Twelve years later Leube established his test-meal as a means of determining the state of motor insufficiency of the stomach, concluding that a normal stomach should be empty seven hours after the ingestion of a meal composed of soup, broth, steak and bread. This is still recognized to-day as a most important means of determining variations in the motor function of the stomach. Leube also at this time analyzed the gastric secretion obtained from the stomach, and in 1883 he developed his well-known scale of the digestibility of various foods, which he earnestly advocated as a means of diet in the treatment of ulcer of the stomach.

Riegel, in 1885, showed the difficulties encountered in obtaining gastric juice by stimulating the gastric secretion by means of ice water, according to the method of Leube. In their classic work on the "Physiology and Pathology of Digestion," 1885, Ewald and Boas presented their experiments regarding the appearance of free hydrochloric acid and lactic acid in the stomach contents, and also drew attention to other important features connected with the chemistry of the gastric digestion. The speaker also referred to the work of Reichmann, and the well-known investigations of Beaumont, Richet and Uffelmann and Penzoldt, and spoke of the gratitude due to J. P. Pawlow and his pupils for the many new facts discovered by them relating to the physiology of gastric digestion. The value of surgical procedures in the treatment of certain disorders of the stomach was first discovered by the great master, Kussmaul, which gave Billroth his inspiration. Woelfler, in 1881, introduced the operation of gastro-enterostomy into surgery; he first performed the operation for inoperable carcinoma of the pylorus in which complete resection of this portion of the stomach was no longer possible. The Heinecke-Mikulicz pyloroplasty was devised by both Heinecke and Mikulicz independently of each other.

STRETCHING OF THE CARDIA IN THE TREATMENT OF CARDIOSPASM AND IDIOPATHIC DILATATION OF THE ESOPHAGUS.

By Dr. Max Einhorn, of New York. This was a detailed report of two cases of cardiospasm and three of idiopathic dilatation of the esophagus successfully treated by repeated stretching of the cardia by means of a metallic cardiodilator constructed by the author. The success of this treatment in these cases had induced him to try a similar method of treatment in pylorospasm, and in some cases of that condition he had apparently had good results by stretching the pylorus.

DUODENAL ALIMENTATION.

Dr. Max Einhorn, of New York, read a paper on this subject and demonstrated an apparatus devised by himself by which nourishment could be injected directly into the duodenum. The method consisted, essentially, of introducing the duodenal pump, which had been originally devised for the purpose of obtaining the duodenal contents, into the digestive tract, and feeding was begun as soon as its end was in the duodenum. The apparatus was left in the digestive system for from eight to twelve days; the thin rubber tube did not inconvenience the patient, and thus he was always ready for the feeding. This was best done at intervals of two hours. After the feeding, water was forced through the tube, and finally air was blown through it and the stopcock was then closed. At a single feeding, between 240 and 300 ccm. of food could be slowly introduced. All fluids must, of course, be introduced at body temperature. Dr. Einhorn said he had successfully used this method of duodenal feeding in three cases, in all of which the usual methods of alimentation were either impossible or undesirable. The advantages of duodenal over rectal feeding were at once apparent, for while the rectum and colon were simply organs for the expulsion of feces and for the absorption of possibly remaining liquids, in the duodenum we had to deal with an organ where the most important digestive juices were secreted.

CARDIOSPASM, WITH DILATATION OF THE ESOPHAGUS.

Dr. Jesse S. Myer, of St. Louis, read this paper, in which he reported ten cases of cardiospasm, seven males and three females, treated by forcible dilatation from above. He emphasized the importance of early diagnosis and early relief of the spasm in order to restrict as much as possible the sac development. It was questionable, he thought, that a sacculated esophagus ever fully regained its normal tone; long after the spasm had been completely relieved, certain symptoms persisted because of this fact. Dr. Myer said that his experience with this series of ten cases led him to the belief that there was a congenital basis for the development of the sacculation. These individuals presented certain well-defined outward evidences which indicated a congenital tendency to a general asthenic state. That cardiospasm was of nervous origin seemed to be the general consensus of opinion. How or why it developed in certain persons, however, had never been satisfactorily explained. Many etiological factors had been considered in the previous case reports, but in none, perhaps, with the possible exception of trauma, had any essential connection been determined. For the development of cardiospasm, as for certain other conditions dependent upon nervous causes, there were probably necessary two factors, i. e., a predisposition and an irritant.

The dilator which Dr. Myer used in the stretching of the cardia in his cases consisted of a double rubber bag with a silk bag inserted between them, and attached to the ordinary stomach tube having no opening in the end.

TORTUOUS STRICTURE INVOLVING THREE AND A HALF INCHES OF THE CARDIAC END OF THE STOMACH TREATED BY GRADUAL DILATATION.

Dr. Bertram N. Sippy, of Chicago, reported this case and gave a demonstration of the instrument he employed.

The papers of Dr. Einhorn and those of Drs. Myer and Sippy were discussed together.

Dr. Charles G. Stockton, of Buffalo, said he had had some experience with cardiospasm and with its treatment by dilatation, and while he had succeeded in some instances, there were others in which the result was not satisfactory. He had had cases where he did not succeed in passing a dilator.

Dr. Allen Arthur Jones, of Buffalo, said the condition of cardiospasm was one of the most difficult that internists and gastro-enterologists had been called upon to treat. Surgical interference in these cases was not altogether satisfactory. The only operation that had been feasible in most instances had not attacked the disease at all, but had simply been undertaken to short-circuit it and feed the patient through an artificial opening. For this operation, it might be said in its favor that some cases of cardiospasm were greatly improved by it, and it was possible in a few instances to allow the artificial opening to close, and thereafter the patient was able to take his or her food in the normal manner. In those cases, one could not help feeling that the condition was accompanied by some intermittent or continuous irritation, either direct or indirect, which gave rise to the spasm and closed the esophagus and cardia, and that the operation allayed the irritation and overcame the spasm.

Dr. John A. Lichty, of Pittsburgh, believed we were coming more and more to feel that gastric ulcer was not a local disease; that it was rather a disease due to constitutional, nutritional disturbance, and if we must feed these patients by the rectal method or starve them, we were to that extent hazarding their chances of recovery by further interfering with their nutrition. Therefore, if this method of Dr. Einhorn's of feeding the patient directly into the duodenum by passing a tube through the pylorus proved successful, we had made a great step in advance in the treatment of gastric and duodenal ulcer.

Dr. A. L. Benedict, of Buffalo, said he had never seen a case of esophageal spasm which required any extreme treatment. One or two passages with an ordinary bougie, a little valerian suggestion, if you pleased, — at any rate, very mild measures were sufficient to relieve the condition. In his own experience, we had a very simple type of esophageal spasm which yielded readily to mild measures of treatment, or else we had to deal with a distinctly organic or at least mechanical obstruction.

Dr. Max Einhorn said that in his paper he had differentiated between cardiospasm and idiopathic dilatation of the esophagus. Cardiospasm was a frequent condition and was easily cured in many instances. It was a neurotic affair. With idiopathic dilatation of the esophagus, however, no matter how originally produced, we found a different picture. These patients were never cured with drugs or suggestive measures, and even the introduction of small-sized bougies would not cure them. When, however, we began to dilate forcibly, overstretching the cardia and making it much larger than normal, then we might accomplish a cure. Cardiospasm and idiopathic dilatation of the esophagus were two entirely different conditions, and we should not mix them up.

Dr. Jesse S. Myer said he was not yet quite clear as to how Dr. Einhorn differentiated clinically between cardiospasm, with dilatation of the esophagus, and idiopathic dilatation of the esophagus. Dr. Myer said his own cases were all examples of cardiospasm with dilatation. If the cardiospasm were primary, then we were perfectly entitled to consider the condition as cardiospasm, with dilatation of the esophagus. Under those circumstances, however, we were not justified in calling it an idiopathic dilatation.

THYROIDISM AS A CAUSATIVE FACTOR OF GASTRIC DISTURBANCE.

Dr. Max Ballin, of Detroit, read a paper on this subject, in which he offered the following conclusions: Thyroidism is a complex of symptoms caused by faulty secretion of the thyroid gland. Besides the principal symptoms (heart, nervous and eye symptoms and goiter), intestinal symptoms (diarrhea, vomiting, etc.), and disturbances of metabolism (loss in weight) were very important; more so, as the latter might occur early in the course of the disease and might be more pronounced than the former. Therefore, the diagnosis in those cases where the intestinal symptoms predominated might be difficult and should be based upon accurate examination as to the existence of slight degrees of goiter, tachycardia and slight eye symptoms. As to treatment, surgical interference, if serum and medical treatment failed, would nearly always cure the intestinal symptoms; in fact, often earlier than the cardiac and eye symptoms. A suitable operation (ligation of the thyroid arteries, resection of the gland or enucleation of tumor from the gland) would be followed most frequently by a surprising gain in weight and would check the acceleration of metabolism with its tissue waste.

Dr. John P. Sawyer, of Cleveland, said that in view of the enormous frequency of thyroidism in the district in which he lived, and in other localities, he did not feel that it was warranted that operative interference should be too frequently recommended. He

had seen instances where large goiters pressed on the trachea and gave rise to pronounced symptoms of obstruction; yet they receded and were symptomatically cured under medical treatment. On the other hand, he could recall a number of instances that were operated on with only temporary relief. He was convinced that the best method of treatment in these cases was not yet generally known, but in most instances he would have grave doubts about recommending thyroidectomy.

DR. J. H. STEALY, of Freeport, Ill., said he had been on the lookout for cases of enlarged thyroid or hyperthyroidism for over twenty years, and up to ten years ago, in his section of the country, not 5% of these cases were ever diagnosed. Now about 60% were recognized. As to the operative treatment of these cases, he was in favor of removing the entire thyroid, with the exception of a small portion, say the size of a penny. He had removed the entire gland in a large number of cases, and up to the present time no symptoms of hypothyroidism had developed by leaving the parathyroids.

DR. BALLIN, in closing, said we should save as much of the thyroid tissue as possible. Nobody to-day was in favor of complete thyroidectomy, which would lead to myxedema. We should only tie as many arteries or remove as much of the gland as was necessary to overcome the symptoms.

ACHLORHYDRIA HEMORRHAGICA GASTRICA AS A SYMPTOM OF CHRONIC GASTRITIS.

DR. JAMES TAFT PILCHER, of Brooklyn, N. Y., read this paper, which gave the result of his investigations made in the pathologic laboratories at St. Mary's Hospital, in Rochester, Minn. He stated that there was a definite entity presented in the stomachs of some patients suffering from various intra- and extra-abdominal pathologic conditions, which was characterized by the absence of hydrochloric acid and the presence of "occult" blood. The condition was probably primarily affected through the agency of a reflex nerve stimulation, inhibiting first the production of free hydrochloric acid to only a moderate degree. This so modified the inhibiting factor of the gastric juice that the necessary conditions for the growth of pathogenic bacteria was furnished, chief among which were to be reckoned the streptococci and colon group, which were present in striking numbers. These direct irritants either themselves or in conjunction with the primary irritative factor, gallstones, appendicitis, pancreatitis, etc., perpetuated the pathologic process until there was an achlorhydria produced. It was most probable that to the erosion following this irritation the presence of blood might be ascribed. In the one hundred stomachs examined at operation, atrophy was never present, nor was there, excepting in one case, any evident insufficiency of the pylorus. There was a general symptomatology accompanying this condition which was very suggestive. The test meal recovered was indicative of the pathologic process in the stomach. There were indications in but seven cases observed that there was no secretion from the stomach mucosa. In others, the presence of mucus, the Biuret reaction and coagulation after activation would tend to show that there was still a moderate degree of enzymatic action. The cases were, therefore, not "achylia gastrica." Many instances were shown which illustrated the progressive, established or retrogressive stages of this condition. Proof of the etiological factors had been demonstrated in the cases operated upon, deduced from their prompt and permanent recovery. The condition was relatively common, approximately one in every fifteen stomach cases examined.

DR. MAX EINHORN, of New York, said that some years ago[1] he published his first article on "Clinical Observations on Erosions of the Stomach and Their Treatment," and five years later[2] his second article on "Further Remarks on Erosions of the Stomach" appeared. In those articles he reported a series of cases in which the presence of particles of gastric mucous membrane appeared in the stomach washings, and these, under the microscope, were found to contain glandular elements. In these cases, the absence of hydrochloric acid was also noted in some instances; in some there was complete achylia and in others hyperchlorhydria. In all of them there were various subjective symptoms of gastric origin, which, together with the small pieces of gastric mucosa, clearly indicated the presence of gastric erosions. The condition was found associated with catarrhal gastritis, sometimes of the alcoholic type. He never had a chance to get an autopsy on any of these cases because all of his patients recovered under treatment, but he did not doubt that a similar condition existed in association with other troubles.

DR. JOHN A. LICHTY, of Pittsburgh, said the one point which interested him particularly in Dr. Pilcher's paper was the relatively large number of cases of achlorhydria or hypochlorhydria, and the few cases of achylia gastrica, and it seemed to him to be within the range of possibility that in the cases he examined the patients were under abnormal conditions and did not secrete their normal gastric juice. Probably, in many of them, serious operations were contemplated; they were in a more or less perturbed state of mind, and this might have disturbed the normal gastric secretions.

DR. JOHN P. SAWYER, of Cleveland, said it was well to keep in mind the fact that repeated examinations, at considerable intervals of time, were necessary in order to determine that given findings were essential or particularly peculiar to the pathological condition determined clinically, or perhaps afterwards recognized at post-mortem.

DR. A. L. BENEDICT, of Buffalo, referred to the unreliability of the blood tests that were employed for occult blood. There were quite a number of different substances that would oxidize guaiac and other things, and some authors gave such a large list, including the ferments, starch, mucus and other substances liable always to be present, that it seemed we must check off our tests for occult blood before we could draw any reliable conclusions therefrom.

DR. PILCHER, in closing, replying to Dr. Einhorn, said that in all the stomach washings he had made in these cases he had never been able to identify any cellular elements that could be referred to the stomach mucosa. He had never seen any clumps of cells or any cells which would in the least give one any idea of the condition of the gastric mucosa. As to the suggestion made by Dr. Lichty that the loss of acidity was possibly temporary and associated with a nervous condition of the patient, Dr. Pilcher said he did not think this was so. This so-called "nervous achylia" was very simply differentiated, and the experienced observer could in most cases tell immediately whether he was dealing with a real achylic stomach or a "nervous achylic" stomach if he would merely make a smear from his residue and stain it with any ordinary stain, and find out what the bacterial content was. In the normal stomach there were very few bacteria, and if we were dealing with a case of nervous subacidity or complete lack of acid due to the same cause, we would not find the enormous number of bacteria that were present in true achylia, nor would we find the pathogenic varieties

[2] Jour. Am. Med. Asso., May 20, 1899.

which were so universally present under diseased conditions.

OBSERVATIONS OF THE VARIABILITY OF THE COMPOSITION OF THE GASTRIC JUICE.

Dr. E. L. Eggleston, of Battle Creek, said that repeated test meals given the same individual under as nearly the same conditions as possible indicated a considerable variation in the acid and pepsin secretion, the secretion being no doubt influenced by psychic conditions. What might be termed the normal secretion in any individual fluctuated to a considerable degree, being influenced both by the mental condition and the kind of food taken. The state of mind — the mental condition — of the patient at the time of the test meal was decidedly unfavorable to normal digestion. As the ordinary test meal was not inviting, this also failed to arouse what Pawlow termed the "appetite juice," and the secretion obtained at the end of an hour might be very misleading. When possible, a specimen of the gastric contents should be taken after the patient had eaten of food that was appetizing and under pleasant conditions. Aside from the psychic influences which caused a variation in the composition of the gastric secretion, it was possible to greatly influence it by the kinds of food taken. It was possible in this way to greatly increase the secretion, or to reduce it almost to *nil*. The author summarized his paper as follows: (1) That with the same food materials there may be quite a marked variation in the percentage composition of the gastric juice, which will result from psychic influences. (2) Iced foods or beverages have only a slight inhibitory action on the gastric secretions. (3) Foods containing free fats in any quantity, when taken either at ordinary temperature or frozen, have a decided inhibitory effect on the gastric secretions. (4) Fruit juices, either frozen or at ordinary temperature, quite markedly increase the secretion. (5) Tincture of gentian compound seemed to have but little effect as a gastric stimulant.

Dr. J. C. Johnson, of Atlanta, said that, when we considered the personal equation and variations in the vital equilibrium, he did not doubt for a moment that we would find a considerable variation in the acid and pepsin secretion, even in the absence of any evidence of ill-health, but in order to determine the exact physiological value of such findings, they must be shown to be on an entirely physiological basis, and, at the same time, such findings must be more or less uniform.

The discussion was continued by Dr. Gustav Baar, of Portland, Ore., and was then closed by Dr. Eggleston.

SOME EXPERIENCES WITH THE EINHORN DUODENAL BUCKET.

Dr. W. G. Morgan, of Washington, D. C., in this paper, reported in detail nineteen cases in which he had used the Einhorn duodenal bucket for the diagnosis and localization of ulcers of the stomach and duodenum. He used both the thread test and the duodenal aspirator, and from his experience with these two methods he realized that Dr. Einhorn had given us means to employ which rendered the diagnosis in these cases comparatively easy and reliable. The application of the thread test was readily applicable to most cases, there being only here and there an individual who objected to the procedure. We could often watch the healing of the ulcer by the lessening of the length and amount of the blood stain upon the thread. Dr. Morgan said he had modified this test by substituting a small split shot inclosed in an ordinary gelatin capsule for the bucket devised by Dr. Einhorn, and he felt that it worked even better, as the patient seemed to experience less difficulty in swallowing it; furthermore, it cost much less to have a number of such tests going on at the same time. Dr. Morgan said that the number of latent ulcers, or ulcers giving few prominent symptoms, was larger than was thought, and that, by the systematic use of the thread test, many cases would be found that would otherwise escape recognition. The test, although sometimes disagreeable, was not seriously objected to and should be instituted at the faintest suspicion of ulcer. Besides being able to localize the ulcer, we were enabled to say with more certainty how the case was progressing and when the ulcer was probably cured.

Dr. Max Einhorn, of New York, said he had employed the thread test in over seventy cases of ulcer of the stomach and could subscribe to its usefulness. In cancer the method could be used advantageously in recognizing and localizing the presence of a growth; it did not tell us whether the growth was malignant or benign, but it indicated the site of the ulceration. He had also found it useful in cirrhosis of the liver, with varicosities and ulceration in the region of the cardia and lesser curvature, even before the occurrence of hemorrhage.

Dr. James T. Pilcher, of Brooklyn, said he had tried the Einhorn thread method as an aid to diagnosis in twenty-five cases of ulcer of the duodenum and in ten cases of ulcer of the stomach, as determined at operation by Dr. Mayo, and its localization of the ulcer in the cases in which he had employed it had not always been quite as definite as one might infer from listening to Dr. Morgan's paper. In the first place, in ulcerations of the duodenum, the bucket did not seem to get beyond the point of the ulceration. In four or five of his cases, however, the ulcer was definitely located by the thread and bucket method, as subsequently proven by operation.

Dr. Morgan, in closing, said that this test was still new and that it would take many hundreds of cases to properly estimate its value, but from his experience he believed it would prove to be one of the most valuable guides in the recognition of peptic ulcer.

HYPERACIDITY AND ABDOMINAL AND PELVIC SURGERY.

Dr. J. H. Carstens, of Detroit, said that cases of hyperacidity that were not relieved by ordinary treatment after a reasonable period of time should be subjected to an exploratory abdominal section, so that the exact diagnosis could be made. Sometimes the operation might fail to reveal the trouble, but in the vast majority of cases it would be found that there were adhesions of the gall bladder, stomach, intestines, appendix or pelvic organs which by reflex action produced that temporary condition which we called hyperacidity. The speaker said that while he discouraged indiscriminate operations as much as any one, he thought that the stomach specialist should make more frequent use of abdominal surgery, which was now free from danger, in obscure troubles of the digestive tract. Dr. Carstens offered the following conclusions: (1) Hyperacidity varied in different individuals. (2) Hyperacidity was a symptom, not a disease. (3) Hyperacidity was most frequently caused by reflex action. (4) Hyperacidity was probably due to irritation of the sympathetic nervous system. (5) Persistent hyperacidity should be cleared up by an exploratory abdominal section.

Dr. Allen A. Jones, of Buffalo, said that in considering this question we should be very careful in deciding what we meant by hyperacidity, and that it was an error to allow the patient to make the diagnosis for us. Many patients complained of extreme gastric

acidity when they were not suffering from that condition at all. If we had a definite reason for feeling that the cause of the excessive acidity rested in some other organ than the stomach, such as the gall bladder or appendix, an operation was certainly indicated, but he protested against opening the abdomen with the idea, as Dr. McPhedran, of Toronto, had put it, of going on a roving expedition.

DR. GUSTAV BAAR, of Portland, Ore., said he had found that excessive indican in the urine was frequently associated with hyperacidity, and, when indicanuria was a constant symptom, he became convinced that it was an indication of the presence of an actual intra-abdominal lesion of the appendix or elsewhere.

DR. J. C. JOHNSON, of Atlanta, said we either had to regard an excess of hydrochloric acid as an entity, or not regard it as such; it was either a disease or a symptom of a disease. In either case, the causes producing this pathological condition must operate in essentially the same way, and whatever the remedy might be, whether the knife, or alkalies, or diet, the essential cause must be removed by the employment of the same factors whose perversion led to its development.

A CLINICAL STUDY OF 600 CASES OF COLITIS.

By DR. GEORGE D. KAHLO, of French Lick, Ind. This paper embraced a résumé of 625 cases of chronic colitis, including both the inflammatory and secretory forms, the subject being treated entirely from the clinical standpoint. Statistics were given showing the sex, age, duration of the disease and the relative frequency of prominent symptoms, as also the occurrence of the more common complications. Errors in diagnosis often led to unnecessary surgical interference. The author believed that treatment should be directed to the local condition, as well as to the neurotic influences that had acted to produce the disturbed secretory function. In prescribing a diet, consideration should be given to disturbances of the digestive function and to the state of nutrition. The effect of mineral waters of the alkaline-saline group, both internally and locally, was also referred to, as were the influences of psychotherapy, massage and hydrotherapy.

DR. JOHN A. LICHTY, of Pittsburgh, discussing the treatment of these cases, said he was a great advocate of the warm oil enema, but, more than that, he believed that the cure lay in the correction of the disturbance of nutrition, such as we often found associated with splanchnoptosis. If you fattened your patient and increased the amount of fat in the abdominal cavity, the mucous colitis would often disappear without any other treatment.

SECOND DAY, TUESDAY, JUNE 7.

ON THE ADAPTATION OF THE HUMAN SALIVA TO DIET.

DR. LAFAYETTE B. MENDEL, of New Haven, in this paper, said that the question of the adaptation of the digestive secretions to the character of the diet had been somewhat debated in recent years. It involved not only an important biological problem, but also suggestive practical considerations in relation to dietetics. Lately it had been reported, for example, that a forced diet of carbohydrates in man increased the content of carbohydrate-digesting enzymes in the saliva. The alleged similar adaptation in dogs had already been subjected to experimental investigation by the author and his colleagues with negative results. New experiments on man, under carefully selected conditions, had failed to show any correlation of enzyme concentration in the saliva with the dietary of the individual. Vegetarians furnished no specific exception in regard to ptyalin secretion. The author stated that his experience corresponded with the results just published by Carlson and Crittenden.

FURTHER OBSERVATIONS ON ALCOHOLIC GASTRITIS AND ITS RELATION TO EXPERIMENTAL GASTRITIS IN ANIMALS.

By DR. NELLIS B. FOSTER, of New York. The author stated that alcoholic beverages, when constantly used to excess, as in the case of certain classes in large cities, was the cause of a gastritis which was well-recognized clinically. The most prominent symptom of this condition was the retching occurring before the morning meal. When the digestive function of these individuals was examined, it was found that there was a diminution in the amount of hydrochloric acid secreted, which, in severe cases, was of such a degree that no free acid was demonstrable in the gastric contents. There did not appear to be a corresponding deficiency in the pepsin secretion. The second notable feature of this form of gastritis was the excessive mucous secretion. There was also to be observed in the majority of cases a decrease in the time that the food remained in the stomach. This had been interpreted as a functional compensation for defective peptic digestion, but might be explained in several other ways.

From the experimental point of view, it was relatively easy to induce in dogs a gastritis by means of dilute alcohol solutions. With dogs having the double stomach (Pawlow), observations might be made as to the effect of alcohol. The initial effect of alcohol was to call forth an increase in the amount of gastric secretion and of acid; if, however, the dose of alcohol be repeated for several days, there was apparent a failure of the stimulus, after a time, to produce the initial effect, i. e., increased secretion, and the amount of mucus secreted became more abundant. This sequence of events was in entire accord with physiological principles of response to stimuli. The ultimate result of oft-repeated excitation was an absence of response following an increased reaction. Applying this principle to the condition observed in animals, it followed that the initial increase of gastric secretion would be of brief duration and then the gastric glands would become more and more refractive to stimulation, as was the case. Ultimately, there would arrive a time, were it possible to continue the experiment over sufficient time, when it seemed most probable that an atrophic gastritis would result. A gastritis marked by much diminished secretion and abundant mucus Dr. Foster said he had noticed in dogs as a sequence in other experiments, and in this state the food remained in the stomach for a briefer period than normal.

DR. JULIUS FRIEDENWALD, of Baltimore, said that about five years ago he published a paper on the pathologic effects of alcohol on rabbits, the work being done in the Pathological Laboratory of the Johns Hopkins University and Hospital, and the results of his work corresponded very closely to those reported by Dr. Foster. The quantity of alcohol taken by the rabbits varied very much according to the size and strength of the animal; certain rabbits were found to be so resistant that they seemed capable of tolerating daily intoxicating doses for an indefinite period.

DR. G. H. BENTON, of Chester, W. Va., said that Dr. Foster spoke of stimulation in reference to the effect of alcohol on the gastric mucosa. The speaker thought this should be regarded as an irritation rather than stimulation. This particular application of alcohol produced an excretion of a thick, tenacious mucus, which was nature's way of protecting the mucous membrane of the stomach.

The discussion was continued by DRS. LICHTY

Johnson, Benedict, Charles D. Aaron, of Detroit, and Nathan Rosewater, of Cleveland.

ANTHROPOMETRIC STUDIES OF THE OSSEOUS PROPORTIONS OF THE HUMAN BODY: WITH A VIEW TO OBTAINING A MATHEMATIC EXPRESSION FOR ENTEROPOSIS.

Dr. John C. Hemmeter, of Baltimore, said that enteroptosis was not an abnormality limited exclusively to displacements of the abdominal viscera, but that the thoracic organs were also displaced as far as the diaphragm and the osseous limitations of the thorax would permit it. By radiographic and other methods of investigation the author had become convinced that enteroptosis was an expression of a general osseous, visceral, nervous and vasomotor abnormality. Acquired enteroptosis was comparatively rare, and then only showed displacements in a few organs of the abdomen. In the acquired form, the thoracic organs, as a rule, were in normal position, and the osseous anthropometric proportions of the body were not found to be deviated from the normal, while in the inherited and more frequent type the thoracic organs were rarely in normal position; there were always several abdominal organs out of position, and the osseous proportions were decidedly abnormal.

Dr. Johnson said he was struck by the frequency with which Dr. Hemmeter had observed displacements of the thoracic organs. In his own observations, which were confined more especially to the abdominal organs, he had never yet failed to recognize some displacement or rather lack of proportion between the thoracic and abdominal organs in patients with enteroptosis or gastroptosis.

Dr. Gustav Baar said he was convinced that most cases of enteroptosis were acquired. The condition was rarely observed in children, at least in his experience, and he believed that the chief causative factor was the pressure of the corset in women or the trousers' strap in men. He believed that very few of these cases were congenital, and that ptosis of the thoracic organs was very rare compared with ptosis of the abdominal organs.

The discussion was continued by Drs. Friedenwald and Pilcher.

CHYLOUS CYST OF MESENTERY.

Dr. A. L. Benedict, of Buffalo, presented a report on a case of chylous cyst of the mesentery in a boy of six years, who was operated on by Dr. Charles E. Congdon. So far as the writer could ascertain, no other case had ever been recognized in Buffalo, although chylous ascites and chylo-thorax had. The largest series of cases in the literature hitherto amounted to 25. Dr. Benedict had, thus far, collected about 65 cases, and had found 3 cases prior to Rokitansky's, in 1848, which had previously been supposed to be the first authentic one. Two indubitable cases were found in the reports of the Paris Academy in 1710 and 1727.

It had been declared that sugar was an essential constituent of genuine chylous effusions, Senator being quoted as authority. Dr. Benedict's case yielded no sugar, and he showed that Senator had been misquoted as considering sugar as anything more than a usual constituent; that sugar had been absent in other cases, and that, on purely physiologic grounds, it could not be considered an essential ingredient. A study of the etiology showed that obstruction of the receptaculum and thoracic duct was rarely a cause, and that, indeed, such obstruction would tend to immediate chylous ascites or chylo-thorax; also, that the theory of embryonal rests was not supported by conclusive histologic evidence. From experimental results it seemed possible that any rise of abdominal pressure might operate, if not to produce the original cavity, at least to cause the development of a macroscopic cyst. Hence, the rather characteristic history of colicky pains might have both a diagnostic and an etiologic bearing, though the frequency of such pains in their association with cyst was too slight to let such a history influence us, excepting in a suggestive way. The physical diagnosis of abdominal cysts, by auscultatory percussion, tuning fork percussion, transillumination, etc., and the exclusion of certain common types of abdominal tumor were discussed. Without claiming that a positive diagnosis could be made, Dr. Benedict thought that in favorable cases operation could be undertaken with the fairly positive diagnosis of some sort of cyst, with the probable diagnosis of mesenteric cyst, and with at least the knowledge that there was such a thing as chylous cyst of the mesentery.

Dr. George W. McCaskey, of Fort Wayne, referred to a case which he saw about twenty years ago in which he made a diagnosis of pericardial effusion. This seemed justified by the muffled heart sounds and by the outline of the cardiac dullness given by percussion. A paracentesis was done, and chylous fluid was obtained. He believed the case was one of chylous pericardial effusion.

Dr. C. F. Korsell, of Chicago, reported in detail a case of chylous ascites in combination with multiple small chylous cysts. The largest cyst formation was found between the layers of the peritoneum in the transverse mesocolon, holding over one quart of oily chyle.

Dr. Benedict, in closing, said that, in a recent review of the subject, he found a record of two cases of chylous cyst of the pericardium.

THE CLINICAL FEATURES OF METASTASES INVOLVING THE NERVOUS SYSTEM SECONDARY TO CANCER OF THE STOMACH.

Dr. Henry L. Elsner, of Syracuse, said that metastases due to malignant disease of the stomach and intestines as they involved the nervous system were exceedingly rare; not so rare, however, as had been supposed in the past. Thorough search would frequently uncover clinical manifestations which made their presence positive. These conclusions were confirmed by post-mortem findings. In occasional cases, metastases of the spine, brain and periphery caused such intense suffering, and their symptoms were so prominent, as to mask partially or entirely the primary growth in the stomach or intestines. Cancers of the stomach might be so localized as to give rise to a few symptoms, while metastases springing from such growths might invade the nervous system, particularly the spine, and lead to a definite train of symptoms. Cancer of the stomach, more particularly, might remain latent during a number of years, during which time metastases followed which might occasionally invade the nervous system. It was important to differentiate the various manifestations associated with pernicious anemia, included under the "*Lichtheim symptoms*," and those due to invasion of the central nervous system, particularly the spine, secondary to cancer of the stomach or intestines.

THE RELATION OF GALL-BLADDER AND DUCT DISEASES TO GASTRIC FUNCTION, BASED UPON CLINICAL AND EXPERIMENTAL OBSERVATIONS.

Dr. J. A. Lichty, of Pittsburgh, read a paper on this subject, in which he offered the following conclusions: (1) A lesion of the gall bladder and ducts may

disturb gastric function. (2) This disturbance may consist of a hypersecretion of gastric juice, especially of the hydrochloric acid, and a diminution of gastric motility, and was in direct proportion to the extent of the pathology present. (3) So-called hyperchlorhydria should be looked upon as a symptom of some organic condition somewhere along the gastro-intestinal tract, and should be treated symptomatically only when organic disease could be excluded with a satisfactory degree of certainty. In the experimental work referred to by Dr. Lichty, it was attempted to show in dogs whose normal gastric secretion had been determined, that by placing infected foreign bodies into the gall bladder, a condition similar to cholelithiasis in the human being occurred, and a change in the gastric secretion and motility took place, much as was found clinically.

DR. ALLEN A. JONES said that in not a few instances he had found that definite disturbances of secretion — not necessarily hyperchlorhydria — or of motion were associated with gall-bladder disease. Furthermore, he agreed with Dr. Lichty that extensive or quite marked morbid conditions of the gall bladder, especially pericholecystitis with adhesions, were not infrequently associated with gastric disturbance. On the other hand, there were cases in which the cause of the gastric symptoms lay in the stomach itself rather than in a morbid condition of some of the other abdominal organs. We should also bear in mind that two or more morbid conditions may exist in the abdomen; the patient may have appendicitis or cholecystitis, and may also have an abnormal condition of the pylorus.

DR. FENTON B. TURCK, of Chicago, said he had no doubt that the infection of the gall bladder in dogs produced by placing an infected foreign body into that organ influenced the secretion and motility of the stomach, but whether there were other factors associated with this had not been touched upon in this research by Dr. Lichty.

DR. J. C. JOHNSON said that in dealing with cases of gallstones and gall-bladder adhesions, we all knew that these conditions produced a certain train of symptoms, but what we wanted to learn was, How did they do it, and, Why did they do it? Before gall-bladder trouble, appendicitis or anything else could produce hyperchlorhydria, there must be a disturbance in metabolism of the secretory cells of the stomach.

DR. C. F. P. KORSSELL, of Chicago, said he had almost invariably found that patients with enteroptosis also suffered from hyperchlorhydria and indicanuria. By keeping this fact in mind, he had relieved many patients who were not benefited by having their appendix removed, or their Fallopian tubes amputated, or their uterus curetted, etc.

DR. JAMES T. PILCHER, of Brooklyn, called attention to the fact that we might have these gastric disturbances due to impaired metabolism of the nerve structures. That was really an organic condition; not merely a functional one. We might have an actual change in the nerve, and in that case it could not be regarded as a functional hyperchlorhydria.

DR. JOHN P. SAWYER, of Cleveland, said that hyperchlorhydria seemed to be regarded by many as a continuing expression of an established disorder. Ought we, however, to regard it in that light? Hyperchlorhydria might be present for a considerable length of time in a given patient under a given set of conditions; at another time it might be absent, and the same patient may have an achlorhydria or a hypochlorhydria. We may have tremendous excursions in this respect due to psychical phenomena.

The discussion was continued by DRS. BENEDICT and FRIEDENWALD, and was closed by DR. LICHTY.

REPORT OF A CASE OF INOPERABLE CARCINOMA OF THE SPLENIC FLEXURE OF THE COLON TREATED WITH NEOFORMANS VACCINE.

By DR. CHARLES D. AARON, of Detroit. The case was one of tumor on the left side of the abdomen which upon exploratory incision proved to be inoperable. Under the use of neoformans vaccine there was an apparent disappearance of the growth and an improvement in all the symptoms.

SOME OBSERVATIONS AND MODIFICATIONS ON THE SCHMIDT TEST DIET.

By DR. G. W. MCCASKEY, of Fort Wayne. The author suggested three slight modifications in the Schmidt test diet. One was the advantage which might be gained by introducing into the diet very small cubes of raw meat which had been soaked in carmine solution for twenty-four hours. These might pass through the stomach in case the latter could not digest the connective tissue, and could be readily recognized macroscopically in the feces as small, red masses. He also advised repeating the test with one half the quantity, approximately, perhaps, 1,200 calories, and if we still got the same results, it would give us a clearer indication in regard to functional impairment. The third modification he suggested was to make it more inviting and palatable by substituting for the purées, gruels, etc., properly prepared potatoes and cereals.

THE RÔLE OF THE BACILLUS COLI COMMUNIS IN DISEASE.

DR. FENTON B. TURCK, of Chicago, in this paper, presented some interesting facts on the rôle of the bacillus coli communis in the gastro-intestinal tract in producing lesions in the liver, kidney, stomach and other organs.

Book Review.

Tropical Medicine and Hygiene. By C. W DANIELS, M.B. Cantab., M.R.C.P. Lond. In three parts, with colored and other illustrations. Part II: Diseases Due to the Metazoa. New York: Wm. Wood & Co. 1910.

The absence of Major Wilkinson from England made it impossible, according to the statement in the preface, for him to share in the preparation of this second volume of the work, in the first part of which he was collaborator. The book nevertheless fully maintains the high standard of excellence set by the first volume [reviewed in the JOURNAL for June 2, 1910]. The second part treats of the metazoan diseases, notably filariasis, trichinosis, ankylostomiasis, myiasis and infections with tapeworms and round worms. In addition there is an admirable chapter on "Snakes and Snake-Venoms" by Lt.-Col. A. Alcock, M.B., LL.D., F.R.S., describing in brief but attractive and complete form the zoölogical characteristics and classification of snakes, the nature of the venoms in the poisonous species, and the general and specific methods of the treatment of snake-bite. This volume should be of special value both to students and to practitioners, and Dr. Daniels and Dr. Alcock are to be congratulated on its successful completion.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 6, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

PROGRESS OF THE EUROPEAN EPIDEMIC OF CHOLERA.

In the issue of the Journal for Sept. 15 we made editorial comment on the source and modes of diffusion of the present European epidemic of Asiatic cholera, and on the measures taken in different countries to prevent its further spread. Since that time the disease has shown little sign of abatement, either in Russia, its primary stronghold, or in Italy, its secondary seat of invasion. Reports from Russia state that, in the week of Sept. 17 to 23, there were in that country 3,038 new cases and 1,474 deaths. During the same period there were in the single province of Amur, Siberia, 26 new cases and 12 deaths. Six cases have occurred at Ferghana, Turkestan. During the week of Sept. 23 to 30, there were 215 new cases in St. Petersburg alone, with 80 deaths, and 393 cholera patients remaining in hospital. Statistics of the Russian sanitary bureau show that since the outbreak of the epidemic there has been a total of 198,246 cases in the empire and 92,329 deaths. These appalling figures, representing the possibilities of pestilential devastation in a country calling itself civilized, further justify our recent characterization of Russia as "medieval in her attitude toward such infections as cholera."

In Italy the situation is somewhat better, though approximately 1,000 persons are said to have died of cholera during the month of September in the region about Naples, where the epidemic has its focus. Latest reports state that on Sept. 27 there were 32 new cases and 22 deaths in the city of Naples, and on Sept. 28, 15 new cases and 9 deaths. At Rome there are said to have been in all only 4 cases and 1 death, the disease being principally confined to southern Italy.

So extensive an epidemic is, of course, a grave menace to adjacent countries and, to a less extent, to those more distant which maintain maritime intercourse with the infected cities. There seems to have been considerable carelessness on the part of Italian officials in guarding against both the importation and the exportation of the disease, and possibly even deliberate concealment of the facts of its prevalence for supposed economic and commercial reasons. The efficacy of intelligently practised measures of sanitary prophylaxis is illustrated by the fact that the other nations of Europe have nevertheless thus far kept themselves free from invasion by the disease. In America the principal risk is from unrecognized cases developing on shipboard after sailing from an infected port, or from "cholera carriers." Stringent measures are being taken by our national authorities and by those of the seaboard states to forestall such possibilities. Emigrants embarking from Naples and Genoa are detained in quarantine, prior to sailing from those ports, for five days, the maximum incubation period of the disease, and, in addition, are subjected to rigid examination on arrival in the United States. American and other steamers have been warned against touching at Naples. Dr. King, of the United States Public Health and Marine-Hospital Service, has been detailed to inspect also the port of Palermo, from which emigrants from the infected districts may sail for this country.

The advent of cold weather and the gradual awakening of official activity will doubtless before long put an end to the Italian epidemic. Meantime vigilant application of recognized principles of prophylaxis should keep America secure from infection by Asiatic cholera from European sources.

NOTES ON THE TUBERCULOSIS CAMPAIGN.

Some medical problems come and go, but the fight against tuberculosis bids fair to go on forever, or until the millennial day of the completely immune race. Meanwhile there are from time to time encouraging tidings of progress in the conflict. The recently published fifth annual report of the associated committees of The Massachusetts Medical Society for the prevention and control of tuberculosis contains account of the opening and valuable service of the three new state sanatoria for consumptives, providing for 850 patients in addition to those accommodated at Tewksbury; of the opening of the new consumptives hospital at Lawrence, Mass., and of the

outdoor camps at Adams, Mass., and at Quincy, Mass. The reports of the several district committees present also interesting data of the work being done in every part of the state. So aggressive and vigorous a campaign can hardly fail of good results. The chairman's report emphasizes furthur desiderata for the future, particularly the need of getting cases under observation earlier in the course of the disease. In a recent letter to the Mayor, Mr. Edward F. McSweeney, chairman of the board of trustees of the Boston Consumptives Hospital, makes similar comment, and suggests the desirability of a more systematic examination of school children in Boston for the detection of incipient tuberculosis and of conditions predisposing to tuberculosis. He also points out the necessity of suitable provision of occupation and environment for arrested cases, to prevent their relapse after supposed cure.

This suggestion calls to mind the valuable possibilities of the Prendergast Camp near Mattapan, conducted by the Boston Association for the Relief and Control of Tuberculosis. The object of this camp is "to offer to men, whose tubercular process has been arrested, a place where they may live under the most favorable conditions." It is intended primarily for recovered cases who have returned to work, but a few incipient or quiescent cases will also be received under suitable precautions. The camp is intended neither for profit nor for charity, but merely to be self-supporting; and a board-rate of $6.00 a week is, therefore, charged. Patients in the camp remain under the care of their own physicians. Applications for admission should be made to the Secretary of the Association, Mr. Seymour H. Stone, 4 Joy Street, Boston. It is provisions such as these that make one hopeful of the outcome in the conflict with tuberculosis, even though the campaign promise to be long and difficult.

MILK TRANSPORTATION RATES.

SINCE the settlement of the milk strike in Boston last spring, we have been happily delivered from apprehensions of a milk famine, and the season has passed without the threatened failure in quantity or quality of the supply. Problems in connection with the price and transportation of milk, however, still remain to be solved, and work on these has been continued through the summer. On Sept. 28 was held the last of a series of hearings before the Interstate Commerce Commission relative to the present shipment rates. Following the termination of the strike in June, there were some changes in the rates charged by certain railroads for the transportation of milk. Against these changes the contractors protested, and the matter was referred to the Commission for investigation. Both sides have presented figures, the one to show that the present rates mean financial loss to the dealers or an increase in price to the consumers; the other to show that lower rates mean loss to the railroads. The question really at stake is the state regulation of methods and cost of milk transportation. Whatever the decision of the Commission on this point, there seems likely to result, in the near future, an increase in the price of milk supplied to the Boston market.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, Sept. 27, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 11, typhoid fever 26, measles 4, smallpox 0, tuberculosis 43.

The death-rate of the reported deaths for the week ending Sept. 27, 1910, was 17.42.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 1, 1910, was 218, against 183 the corresponding week of last year, showing an increase of 35 deaths, and making the death-rate for the week, 16.95. Of this number 120 were males and 98 were females; 210 were white and 8 colored; 148 were born in the United States, 70 in foreign countries and 0 unknown; 52 were of American parentage, 139 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 34 cases and 2 deaths; scarlatina, 22 cases and 0 deaths; typhoid fever, 16 cases and 4 deaths; measles, 3 cases and 0 deaths; tuberculosis, 66 cases and 16 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 22, whooping cough 0, heart disease 23, bronchitis 5. There were 10 deaths from violent causes. The number of children who died under one year was 59; the number under five years, 72. The number of persons who died over sixty years of age was 57. The deaths in public institutions were 87. Cerebrospinal meningitis, 1 case and 1 death. Anterior poliomyelitis, 2 cases.

Of the above infectious diseases the following

were non-residents: Consumption, 1 case. Scarlet fever, 1 case. Typhoid fever, 1 case and 1 death.

Deducting deaths of non-residents, the total is 191 and the death-rate is then 14.85.

HARVARD MEDICAL AND DENTAL SCHOOLS. — The Harvard Medical School opens the new year with 267 students, 13 less than last year. The Dental School begins the year with 106 students, 21 more than last year.

UNITED DRUG CONVENTION. — The annual convention of stockholders of the United Drug Company, held in Boston last week, was attended by nearly one thousand representatives, coming from every state in the Union, and from Canada. At the sessions questions of the preparation and sale of drugs and of the policy and government of the company were considered. It was unanimously voted that the next convention be held at Richmond, Va.

ETHER DAY AT THE MASSACHUSETTS GENERAL HOSPITAL. — Members of the medical profession are invited to attend the Ether Day exercises to be held at the Massachusetts General Hospital on Oct. 15, 1910, at 4.30 P.M. The address will be by Dr. George W. Crile, of Cleveland, Ohio. Admission will be by ticket only. Application for tickets should be made to Dr. Frederic A. Washburn, Resident Physician.

RETIREMENT OF DR. AUSTIN PETERS. — The Daily Press announces the appointment by Governor Draper of Mr. Walker, a farmer of Burlington, Mass., to succeed Dr. Austin Peters, the present chief of the Cattle Bureau. With the well-recognized importance to the human race of protection from the diseases of the domestic animals, this change is most unfortunate. Dr. Peters has and deserves the confidence of the medical profession.

BOSTON HOSPITAL CONCERTS. — The first of this season's series of concerts, provided by the Boston Hospital Music Fund, was given on Sunday, Oct. 2, at the Home for Aged Women, Revere Street. Further concerts will be given during the current month, as follows: On Oct. 9, at the Home for Aged Couples, Roxbury; on Oct. 16, at the Cushing Hospital, Roxbury; on Oct. 23, at the Woman's Charity Club Hospital, Roxbury; on Oct. 29, at the Boston State Hospitals for the Insane; and on Oct. 30, at the New England Baptist Hospital, Roxbury.

ILLEGAL SALES OF MILK AND COCAINE. — In the Roxbury district court last week three dealers of that region, whose licenses to sell milk had been previously revoked for disobedience to the regulations of the Board of Health, were fined $50 each for continuing to offer milk for sale. In the Boston municipal court, Carl Foley was found guilty of having made an illegal sale of cocaine in Boston on Sept. 9, and was sentenced to imprisonment for four months. Rigorous enforcement of food and drugs laws is essential for the public safety.

ABOLITION OF PUBLIC DRINKING CUPS IN MASSACHUSETTS. — The new regulation of the Massachusetts State Board of Health, prohibiting the use of common public drinking cups throughout the state, became operative on Oct. 1. This law applies to schools, hotels, theaters, halls, railway stations and other public buildings, to parks and highways, and to railroad cars, boats and other public conveyances. It is gratifying that Massachusetts has so soon followed the lead of other states in this desirable measure of hygienic reform.

OYSTER BEDS CONDEMNED IN RHODE ISLAND. — Report from Providence, R. I., states that on Sept. 27 the Rhode Island Board of Shellfish Commissioners condemned 275 acres of oyster beds at Bristol, in that state, as unfit for use on account of pollution by sewage from the city. It is matter of congratulation, not only to residents of Rhode Island, but also to oyster consumers elsewhere, that their interests are being so observantly safeguarded by local authority.

POLIOMYELITIS IN RHODE ISLAND AND VERMONT. — In the issue of the JOURNAL for Aug. 25, we noted the appearance of epidemic poliomyelitis in Providence, R. I. Recent report states that during the months of August and September there were 81 cases in that city, with 9 deaths. Ten cases have occurred in Newport, R. I. The total number of cases reported to the Rhode Island State Board of Health since June 1 is 163. Report from Montpelier, Vt., states that there have been upwards of a dozen cases of poliomyelitis in that state this summer, with 2 recorded deaths. The progress of these minor epidemics, *pari passu* with the more extensive one that has prevailed in Massachusetts, emphasizes the unquestionably infectious nature of the disease and the importance of its continued clinical and experimental study.

AMERICAN ASSOCIATION OF CLINICAL RESEARCH. — The second annual convention of the American Association of Clinical Research was held last week in Boston in the building of the Society of Natural History. Among the papers presented was one by Dr. E. S. Bailey, of Chicago, on "Research Work in Radio-Activity"; one by Dr. R. R. Smith, of Boston, on "Research Work in Mechanical Therapeutics"; one by Dr. C. H. Wintch, of Newark, N. J., on "Turpentine Poisoning"; and one by Dr. L. V. Briggs, of Boston, on "Recent Researches in Mental Medicine." A report was made by Dr. W. H. Ketchum, of Hopkinsville, Ky., on the use of the hypnotic state in diagnosis, furthur consideration of which was deferred till the next convention. Dr. A. R. Peebles, of Boulder, Col., was elected president for the ensuing year; Dr. I. S. Wile, of New York City, and Dr. J. F. Cobb, of Chicago, vice-presi-presidents; and Dr. James Krauss, of Boston, secretary and treasurer.

NEW YORK.

RATS AND MICE AND A STRIKE. — A strike is threatened among the stenographers and other female employees at the Capitol in Trenton, N. J., because the State Department of Health, having, after some difficulty, secured the necessary permission, is about to establish, on the roof of the building, quarters for rats and mice, among other animals, kept for experimentation.

AN EVASION OF REQUIREMENTS TO PRACTICE. — Justice Hendrick, of the New York Supreme Court, has signed an order denying the application of a certain physician who passed the New Jersey examination, and is licensed to practise in that state, for a writ of mandamus compelling the regents of the University of the State of New York to admit him to the practise of medicine in New York. The regents had refused his application on the ground that he took two out of the four years' college attendance required by law at the Boston College of Physicians and Surgeons, an institution not registered with the board of regents as having a sufficiently high standard of instruction, and that it would simply be an evasion of the requirements to allow him to practise by way of comity with the state of New Jersey.

THE ENTERING CLASS AT COLUMBIA. — The opening exercises of the medical department of Columbia University (the College of Physicians and Surgeons) were held on Sept. 29. There was a slight falling off in the registration, the first-year class showing an enrollment of 75, as against 90 in 1909, a circumstance attributed to the more rigid requirements which went into force the present year. The address on this occasion was by Dr. William G. MacCallum, professor of pathology, who took for his subject, "The Future of Medicine." In the course of it he expressed the opinion that the physician of the future would be employed principally to prevent disease, not to cure it, and he urged that marriages of deaf mutes, imbeciles, epileptics, degenerates and defectives in general should be prohibited by statute.

THE STRAUSS MILK CHARITY. — The regular summer stations of the Strauss Milk Charity have already been closed, but, in consequence of the appeals made to him, Mr. Strauss has decided to keep the seven stations from which pasteurized milk has been dispensed throughout the year in operation until Nov. 1. By that time the committee of which Mrs. J. Borden Harriman is chairman, it is expected, will have completed a plan to carry on the work heretofore conducted by Mr. Strauss under his own name. On behalf of the latter it is stated that while he is unwilling to bear the brunt of such opposition as in the past has been directed against him personally, he would lend any substantial financial backing to this charity if it were carried on in the name of a committee or organization. It is also stated that Health Commissioner Lederle has expressed much interest in the proposed undertaking, and that to the original committee have been added the names of some forty persons, many of them representing charitable organizations.

UNEXPECTED RESULT OF CAMPAIGN AGAINST IMPURE MILK. — One rather unexpected result of the campaign against impure milk which has been carried on of late in the city has been, it is found, that in quite a large number of instances, mothers of the tenements, in their efforts to save their children from the ill-effects of bad milk, are now trying to eliminate milk from the family diet and are substituting tea and coffee in its place. To such an extent has this reactionary movement spread that the consumers' section of the New York Milk Committee has deemed it necessary to come to the defense of milk, and has accordingly issued for distribution a pamphlet, bearing the names of Dr. Harvey W. Wiley, of the Agricultural Department's Bureau of Chemistry; Dr. H. C. Sherman, of the Department of Chemistry, Columbia University; Dr. Ira S. Wile, of the Department of Diseases of Children, Vanderbilt

Clinic, and others qualified to speak with authority on the subject, which warns the mothers against coffee and tea, and sets forth the nutritive value of milk and its peculiar adaptedness for the wants of infants and young children.

1. Hoover does not decry the use of the blood-pressure apparatus, but thinks, however, that no instrument is as valuable as the educated finger. He advises the use of the femoral rather than the radial or brachial for palpation.

5. Matthews, examining one thousand cases of goiter, finds that the average frequency of symptoms of pressure on the nerves was directly proportional to the size of the lobes. Exceptions came in small hard lobes which are even more apt to harm nerves than large soft ones. The position of the lobe is important, those situated nearest the clavicle giving the most trouble. Men are about three times as liable as women to paralysis from goiters of the same type. Operation relieves those in which the pressure has not been long enough to produce degeneration of the nerves. Early laryngoscopic examination and operation may prevent complete paralysis.

9. Waugh concludes that in serum diagnosis of syphilis a positive result is an indication that the disease is still active and that more treatment is necessary. One negative result should not suffice in any suspected case of syphilis. The test should be repeated at intervals of six months for the first year after all treatment is discontinued, and afterward at longer periods. In quite a large percentage of cases two years of specific treatment is not sufficient to insure a negative result from the test. The tendency at the present time is to under-treat rather than to over-treat these cases. The Wassermann reaction is of inestimable value in obscure cases of syphilis and in differential diagnosis.

10. Corbus is enthusiastic over the Wassermann test, which he has used for two years as the original test without modification. It is especially valuable as a guide to treatment. We may now begin treatment early, energetically and watch our results with exactness. [E. H. R.]

14. Matthews, A. C. *A Case of Fracture of the Thyroid Cartilage with Prompt Recovery.*

3. Dyer and Hopkins give an excellent review of the symptoms and lesions produced by the lepra bacillus. They plead for a more intimate knowledge by the general practitioner, as cases are becoming more common in this country. The great trouble in diagnosis lies in the number of atypical cases. A change in type from the tubercular to the anesthetic form may take place, or the two may occur together. These variations are not often enough recognised.

4. Somers states that edema of the uvula may occur as a traumatic lesion from over or improper use of the

voice. It is often a prodromal symptom of acute articular rheumatism. In chronic specific infections, as tuberculosis and syphilis, it may occur late and is significant of grave local lesions and destruction of tissue. It may be the only symptom of approaching uremia. It is rare in acute nephritis, but occurs in scarlet fever as a sign of profound intoxication.

5. Hartz selected twenty cases of non-active, chronic and generally favorable tuberculosis of the lungs for a trial of the mercury succinamid treatment advocated by Wright, U. S. N., and found that, although they showed a temporary improvement, yet all eventually began to deteriorate almost in direct proportion to the number of injections they had received. The deterioration was more marked and rapid than in others who had not had the mercury. He therefore concludes that mercury as recommended by Wright has utterly failed as a specific agent in the treatment of pulmonary tuberculosis, and is positively injurious to the patient.

7. Wilson and Willis, from the examination of operation specimens, conclude that the relationship to cancer of simple chronic irritation of the unbroken free surface of the mucosa of the alimentary canal, as indicated by clinical data, is not readily demonstrable pathologically. Scar tissue at the bases of ulcers, obliterations of the lumina of appendices and diverticula segregate portions of mucous epithelium from the neighboring mucosa and from the lumen of the alimentary canal. These portions of segregated mucous epithelium tend (*a*) to degenerate from pressure and diminished blood supply; or (*b*) to proliferate and infiltrate the surrounding tissues, thus forming cancer. [E. H. R.]

7. STAVELY, A. L. *Chronic Gastro-Mesenteric Ileus.*
8. RICHARDSON, E. H. *Parasitic Myomata. With Report of an Unusual Case.*

3. Frazier finds that section of the posterior roots of the spinal cord in some cases gives marked relief from spasticity, but that operation must be carefully followed up by persistent after-treatment in the form of education of the muscle groups. Benefit is not immediate. Much pain may be expected until improvement finally sets in. Voluntary movement is generally restored in part, but restoration of useful function cannot always be expected.

6. Scudder, after a concise review of the pathology, symptoms and treatment of congenital pyloric stenosis in infants, reviewing the post-operative history in fourteen cases, concludes that the presence of the gastro-enterostomy stoma does not alter the metabolism of the infant to its detriment, and from x-ray pictures and one autopsy case demonstrates that the pyloric tumor probably persists even into adult life. 25. WENCKEBACH, K. F. *A New Stand for X-Ray Work.*

10. Dominici describes remarkable results obtained by means of radium therapy in some cases of malignant disease, including lymphoma of the parotid, sarcoma of upper jaw, sarcoma of the neck, epithelioma of the nose and others. The article is illustrated by means of an excellent plate.

14. Pirie describes a peculiar form of excessive sweating which he calls "hyperidrosis frigida," characterized by its increase by cold and its entire cessation at night. Such cases which he presents suffering from this condition have been entirely relieved by x-rays.

15. Turner and George present preliminary results of work done on the effect of x-rays in therapeutic doses on the growing brains of rabbits. They demonstrate certain gross changes, but come to no definite conclusions. They advise further work on the subject.

17. Jordan makes the remarkable statement that "the Röntgen-ray method is an indispensable diagnostic aid in all pulmonary diseases and that it is capable of demonstrating the exact position and extent of the pulmonary lesion even in very early cases of phthisis." He goes on to state, however, that the healed lesion may make a shadow similar to that of the earlier active lesion. These two statements do not seem to agree.

18. Orton regards the x-ray as an aid to diagnosis in early tuberculosis, but by no means the most important factor. He discusses various points in the early diagnosis of this condition by means of the x-rays.

22. Barclay discusses the stomach in normal and pathological conditions as seen by the x-rays, with special reference to the diagnosis of pyloric obstruction, ulcer and cancer. He believes that the x-ray examination by means

of the bismuth meal will give much information in experienced hands, but that the method is a difficult one. [J. B. H.]

2. Munk describes a substance which resembles fat but which can be separated from it by the polarization microscope. This substance called "lipoid" occurs normally only in the suprarenals. Under certain conditions of disease it appears in other organs and vessels. This author has found it in the urine and sputum of patients and thinks that the examination of a urinary sediment with the polarization microscope for lipoid is of diagnostic value in making a differential diagnosis between acute and chronic nephritis.

5. Tsuzuki found that patients recovering from typhoid fever became free from the bacilli in their stools and urine more rapidly if they had administered to them calcium iodide or arsenious acid. These drugs seem to act much more actively *in vivo* than *in vitro*. This is rather in the form of a preliminary publication, but if verified by others it ought to prove of value in the attempt to eradicate bacillus carriers. [C. F., Jr.]

1. After relating the progress that has been made in the surgery of blood vessels, the author presents two cases. The first was a punctured wound of the left femoral artery in the region of Hunter's canal. This wound was repaired with silk sutures, and complete recovery followed. The second case is mentioned to show that even the largest veins may be penetrated without immediate fatal hemorrhage, for the superior vena cava was penetrated. This was not diagnosed until after death, which followed some sixteen hours after his injury. [J. L. H.]

Correspondence.

WINCHESTER AND THE ARTHURIAN REGION. SALISBURY. STONEHENGE. GLOUCESTER. BATH.

[*From Our Foreign Correspondent.*]

Gloucester, Sept. 12, 1910.

Mr. Editor: Our past ten days of travel have taken us through the regions particularly associated with Arthurian romance, and it has been pleasant in connection with them to recall the half-mythical, half-historic legends of the British king and his knights which have formed the material of our greatest racial and national epic.

From Southampton one may go up the River Itchen, memorable for its later piscatorial association with Sir Izaak Walton, to Winchester, supposed to be the "many-tower'd Camelot" of Arthur. There is little in the busy town of to-day, however, to recall the "blameless king" and his vanished state. Indeed, modern Winchester has much more obvious reminiscences of another monarch, Alfred the Great, who made it the capital of his kingdom of Wessex, and issued thence his four famous Anglo-Saxon translations. His heroic statue, erected at the millennium of his death, dominates the market-place and principal street, and sends westward over land and sea the benediction of his uplifted sword-hilt. Even after his time, during the ascendency of the Mercian kings, the city retained much of its political importance and was a headquarters for William the Conqueror and his Norman successors until the seat of government was finally transferred to "the place which now is this world's hugest." Of all this royal magnificence there is now scarcely any trace, and castle and palace have been outlasted by the grim, massive cathedral, where, among others of note, the good Sir Izaak lies buried, and by the famous Winchester School, founded by Bishop William of Wykeham, whose motto, "Maners makyth Man," deserves to rank with the more practical apophthegm of another ecclesiastic of his time, "Serve God and be Chearefull." Both might be pondered and applied to advantage in our own day. Few men have succeeded as well as Wykeham in impressing their own personality on institutions which they have shaped, and to this day the graduates of the Winchester School and of its scion, New College, Oxford, form throughout England a clan of Wykehamites whose loyalty to each other and allegiance to their school and the principles of its founder are remarkable. A visit to the pleasant, venerable buildings of this ancient school is well rewarded, not only by the interest of observing its preservation of old usages and customs, such as the serving of food on wooden trenchers, but by the inspiration of the noble inscriptions under its portals to the memory of alumni who have sacrificed life or fortune in the honorable service of their country.

Among so much of medieval interest there is small wonder that everything but the memory of Arthur has perished out of Winchester, and one must have recourse to imagination to restore the Camelot of old. In this

instance the trick is not so difficult, and for once the fancy cheats " as well as she is famed to do." Close by the river stand still the ruins of Wolvesey Palace, a Norman structure of the twelfth century, and if one walk out of the town and down the stream at sunset, when the light blurs the outlines and glorifies the semblance of everything it touches, one can transform their fragments at will into the stately towers and gates of King Arthur's fabled castle. As we went one afternoon on such an excursion, we met, in the person of a small urchin, an enthusiastic modern disciple of the " compleat angler " who later gave new fame to these waters. Stopping by the bank to inquire of his success, we asked him what he was fishing for; to which he solemnly replied, " Trite," a plural which was novel but might perhaps be justified on the analogy of " kine " and " mice." As we came back, after this episode, the mist-wreaths were already rising from the river and twining among the reeds along the shore, and in the evening twilight it was not hard to see once more the lovely Lady of Shalott drifting down out of the dusk on her barge to the jasper gates of Camelot.

Not many miles from Winchester is Salisbury, a rather prim and quiet town with a beautiful " mercat-cross," in the shape of a stone crown, like that of Chichester, and an elegant cathedral that suns itself in a broad, open green, surrounded but not hidden by noble elms and beeches. In this cathedral, near the chancel-rail, is buried

" The subject of all verse,
Sidney's sister, Pembroke's mother,"

the Countess of Pembroke, for whom the " Arcadia " was written by her gallant and chivalrous brother, Sir Philip Sidney, the knight-errant of English poets. By a curious coincidence, we learned that a Boston physician had been married in this church five years ago, and found the record, with his name, on the register. After all, personal associations, whether past or present, are the strongest links that draw us to old places as well as to old friends.

Even more interesting than Salisbury, because unique in kind, is Stonehenge, the most impressive and ancient human monument in England. One visits it from Amesbury, a quiet, sunny little village, preserving, in slightly altered form, the name of Almesbury Abbey, whither the guilty Queen Guinevere fled after the discovery of her treason with Launcelot, and where, after Arthur's last battle, she " let make herself a nun." Of the old nunnery no trace remains, but the present small abbey church doubtless stands upon its site, and seems to harbor some measure of the peace to which she passed.

Stonehenge itself is about two miles from Amesbury, standing solitary and inexplicable in the open rolling country of Salisbury Plains. As you first catch sight of it from a distance, it looks almost insignificant; but as you approach, it acquires dignity; and when you stand close to its enormous shafts, you begin to appreciate its archaic grandeur. Dozens of theories have been propounded by antiquarians and geologists to account for its existence. The probability seems to be that at least some of the gigantic monoliths of which it is built were brought by glaciers during the Ice Age from Iceland, and subsequently left on the alluvial plains of southern England. Here they were found by the Phenicians at the time when this ancient race, near the dawn of history, apparently roamed and settled sporadically over a large part of Europe. With them the Phenicians constructed Stonehenge as a temple of sun worship, in the form of two concentric circles enclosing two ellipses. At the westerly focus of the inner ellipse was an altar, upon which, on the longest day of the year, the rising sun casts the shadow of a single stone, now called the Friar's Heel, set up some distance to the eastward. Midway between this stone and the outer circle of the temple is a large, flat slab on which the victims are supposed to have been slaughtered and their viscera then carried up in processional to be burned on the altar. It is a striking coincidence that the date assigned to this structure by archeologists on the basis of stone implements and utensils dug up in the vicinity, and that computed by astronomers from the present slight deviation of the shadow, owing to slow cyclic change in the position of the solstices, is the same, — 1700 B.C.

The Phenicians passed away; the Celts came, whom we think of and know as the native, aboriginal Britons. The Druids, the priests of their national religion, found Stonehenge ready to hand, and, knowing nothing of its astronomic significance, used it as a temple for their own form of worship. Their victims were probably killed on the same slaughter-stone, but, instead of being burned, were buried in the peculiar tumuli or barrows which still remain in the meadows round about. Then came the Romans, drove the Britons to the fastnesses of Scotland, Wales, Cornwall, and Brittany, built up a civilization of their own and were in turn displaced by the invading hordes of Jutes, Angles, Saxons and Danes. And still Stonehenge remained a puzzle and marvel to successive races, remained through the Norman conquest and the vicissitudes out of which has developed the England of to-day. Many of the monoliths have fallen, but the original plan is perfectly distinct. When one contemplates this colossal monument, which in its utter simplicity of construction has persisted through the storm and stress of thirty-six centuries, the remote antiquity of Arthurian legend seems recent in comparison, and if one reflects that these stones of which it is built were probably brought two hundred thousand years ago by glaciers from the strata in which they were formed in æons past, one begins to realize how small a moment the whole of human history is in the space of measurable time. Such a contrast reduces the greatest individual achievement to nothing, and makes Stonehenge the peer of the Sphinx and the Pyramids and the image of Ozymandias.

From Stonehenge it was a long journey, and a much longer lapse in thought, to Camelford, the little hilly town in Cornwall near which is reputed to have been fought Arthur's " last, great battle in the West." Of course, there is nothing now but tradition to tell the tale, and we had not even time to seek out Dozmare Pool, locally regarded as the " murmuring mere " into which Sir Bedivere cast the brand Excalibur. For us Camelford was only a stopping-place from which to continue our way by coach to Tintagel.

Tintagel, with which Tennyson has familiarized us as " dark Dundagil by the Cornish Sea," remains not only one of the most romantically beautiful spots in England, but one of the most tangible memorials of a shadowy and legendary past. On a huge, rugged promontory thrust out into the roaring ocean from a shore of dark, bristling, slaty reefs, stand the ruins of a castle of unknown date, which, though doubtless not the original structure, probably occupies the site of the ancient castle of the kings of Cornwall. The ceaseless action of storm and waves has battered down the ramparts and carried a large part of the once extensive fortress into the sea; but the round keep on the shoreward side still commands the dark, narrow ravine that leads down to it from the land. The castle should seem impregnable, and is said to have been entered never by force and only once by fraud, when Uther Pendragon made his way in by representing himself as Gorlois, the King of Cornwall, whom he had just slain in battle. In this castle was born Arthur, the child of Uther and of Igraine, the Cornish queen, and from here he is fabled to have been taken at night by Merlin, who entrusted him secretly to Sir Ector to be nurtured and educated until it should be time for him to claim his kingdom. At the base of the cliff on which the castle stands is a wicked cave, tunnelling completely through the promontory, slippery with seaweed and dripping with ooze at low tide, and at high tide filled with thundering surf and dashing boulders; and this is still known as Merlin's Cave, for here the great wizard lurked till he could obtain the child. That romantic episodes should have occurred in such an environment seems inevitable, and from the prosaic certainties of to-day it is fascinating to speculate back into the haze of a bygone age and conjecture what may have been the basis of actual fact underlying so much that is beautiful in song and story.

In later time, after King Arthur had come to his own and had established the Round Table, Tintagel Castle remained the seat of the kings of Cornwall, and became the scene of the more tragic romance of Iseult, the wife of King Mark, and Tristram of Lyonesse. That story, unfortunately more familiar to most of us in the foreign garb of the opera " Tristan und Isolde," is still one of the most perfect types in literature, and its association with Tintagel makes the old castle doubly interesting. As one stands on

the headland looking across towards the Irish shore, one can see in any passing boat the silken-sailed vessel bearing Tristram and Iseult, upon whom the sea has worked its immemorial magic.

From Tintagel our road lay along the coast, through Cornish and Devon villages of the greatest charm and beauty, but without particular interest of association. At Taunton, the county-town of Somersetshire, we came, singularly enough, upon two totally diverse objects of professional interest. In the local museum here is preserved the trunk of a young ash tree cleft for the cure of congenital hernia. There appears to have been a rather widely diffused superstition in England that if a child with a hernia be passed thrice through a sapling thus cleft, and if the tree subsequently grow together again, the child will be healed of his infirmity. In this instance, the cure must have failed, or else some enterprising folk-lore student secured the specimen too early and aborted the result, for the split in the trunk still remains widely enough separated to admit the passage of a full-term baby through it with ease. We were credibly informed that this practise has been followed in all good faith by inhabitants of the vicinity until within very recent years. It is quite conceivable that the percentage of spontaneous cures of infantile umbilical hernia, and of hydrocele incurring the still customary parental diagnosis of hernia, was sufficiently great to establish and maintain the reputation of this procedure, which, like other primitive therapeutic measures, apparently had its origin in the idea of transferring the ailment in similar form to some creature or thing, in which it might become cured by natural process. Our other object of professional interest at Taunton was a sign-board on the highway advertising the "Harvard Teeth Institute." Apparently the merits of American dentistry and of at least one American school are not unknown in Somerset, or their possible commercial value unappreciated.

A forenoon's journey from Taunton took us once more out of the mercantile atmosphere of a busy market-town back to the dreamland of medieval romance, to Glastonbury, the Avalon of Arthurian tradition. Geologic and climatic change, as well as the growth of so-called civilization, have altered it somewhat from

> "The island vale of Avalon,
> Where falls not hail, or rain, or any snow,
> Nor ever wind blows loudly";

yet it is still as lovely a spot as is to be found in all of merry England, and lies

> "Deep-meadow'd, happy, fair with orchard-lawns,
> And bowery hollows, crown'd with summer seas."

It was always hard to understand how Glastonbury could ever have been an island, but the solution becomes easy at a glance when one ascends the Tor and looks down on the great alluvial plain that encircles the four hills, — Tor, Chalice, Edmund's and Wearyall, — between which lies the little town. In Arthur's time this plain was all under water, and Avalon with its hills formed a sheltered "island-vale," to which the king was brought "to heal him of his grievous wound." To this island also was reputed to have come some centuries earlier Joseph of Arimathea, bringing with him as a supremely precious sacred relic the Holy Grail. His descendants were supposed to have built on Chalice Hill the Grail Castle and to have dwelt there as guardians of the Grail and kings of the surrounding country, until the holy vessel was lost through the misdemeanor of King Pelles, about the time when Arthur came to his kingdom. Hence the quest of the Grail became one of the favorite exploits essayed by knights of the Round Table; and hence, after his last battle, Arthur was appropriately taken to Avalon. Of his reputed grave there, and of Queen Guinevere, and of the mythical castle, there is, of course, no trace to be found. In later days, when the waters had receded, and Glastonbury had ceased to be an island, a monastery was established there, which in time grew into the most splendid mitered abbey of England. Here St. Dunstan lived and vanquished the devil in summary fashion, and hither came pilgrims "from every shires ende" to visit the famous shrine. Wearyall Hill still preserves the memory of their hardships, when from its summit they first caught sight of their goal and began the last stage of the journey. Yet apparently the creature comforts of wayfarers were not wholly neglected even in those days, for we lodged in the town at the "Pilgrimes Inn," built in 1425 for the accommodation of palmers coming to the shrine, and if they were as well housed and fed there as we, their lot could not have been a very hard one.

Of the vast church and accessory buildings of Glastonbury Abbey, only a few fragments are still preserved, but they are enough to give a conception of its former lofty magnificence and beauty. Unfortunately, human progress seems inevitably to involve the sacrifice, not only of human lives, but of many of the finest fruits of precedent human genius. Henry the Eighth, that uxorious and iconoclastic monarch, to whom the world owes so much, yet who ruthlessly destroyed so many of its noblest monuments, suppressed the abbey during his wholesale measures in the sixteenth century, and hanged its last abbot on Glastonbury Tor, saying that he would make a scarecrow of him to frighten his fellow-prelates. After this, the days of the abbey were numbered, and the unthinking and unfeeling generations completed the work of plunder by pillaging the ruined walls of rare tracery and exquisite carving to be used for macadamising the roads of the neighborhood.

After so distinguished a history and so calamitous a visitation, Glastonbury and its abbey remain, however, rich in stirring memories and associations. Whether Arthur were really ever buried here or not, his spirit has become the *genius loci*, as that of Friedrich Barbarossa has of the Harts Mountains. And if ever one should wish to appreciate the significance of Arthurian romance, or look for the return of Arthur and his time to this earth, it could be in no other spot than in this isle of Avalon.

It is singular that the translation and apotheosis of Arthur should have occurred so near the site of one of the earliest and perhaps the most authentically historic of the episodes in his career. Less than thirty miles from Glastonbury, rising greenly wooded behind the city of Bath, is Bath Mountain, where was fought the celebrated battle of Mons Badonis, mentioned by Nennius as the last of a series of engagements which marked the victory of British resistance to Roman rule and ended in the establishment of King Arthur upon his throne of sovereignty among a number of petty British chieftains. The modern city of Bath, however, has many more reminiscences of the Georgian than of the Arthurian era, and the spirit of Beau Nash still pervades its abbey and its pump-room, despite the Roman excavations that reveal the luxury of earlier conquerors. The waters still bubble up hot and copious as they were doing fifteen centuries ago, at the rate of half a million gallons a day; and, whether their efficacy be due to chalybeate virtue or to a radio-activity unsuspected in the days of the Cæsars, their healing properties are still eagerly sought by those who are not sick enough to be abed nor poor enough to be obliged to work for a living. Doubtless, as the Pindaric quotation over the door of the pump-room says, "Water is best," but one need hardly come to Bath to learn that truism.

One other place of Arthurian association deserves mention in the chronicle of our journey, and that is "old Caerleon upon Usk." Here once was Arthur's summer palace, and here still is preserved the local memory of his presence. Caerleon to-day is a sleepy little hamlet, dozing in the leafy valley of the Usk that rivals the more celebrated Wye in beauty. It has but a few hundred inhabitants, and contains a single, diminutive inn, with sanded floors and deal tables and walls adorned with scripture texts and the warning that "swearing is strictly prohibited." There seems much doubt whether the circumvallated mound, still pointed out in a meadow as King Arthur's castle, were ever a castle or had anything to do with Arthur. Be that as it may, the name is still there to conjure with, and in romance a name is everything. Caerleon upon Usk is a phrase to recall all the buoyancy of boyhood, and the sunny beginning of adventures "once upon a time." If ever there were an enchanted palace, it should be here, and there is no better place than here to take farewell of King Arthur, the secret of whose immortality is that he embodies as an ideal the eternal youth and hope of man.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED SEPT. 21, 1910.

GASSAWAY, JAMES M., surgeon. Granted one month's leave of absence from Sept. 7, 1910, on account of sickness.

WHITE, J. H., surgeon. Granted ten days' leave of absence from Sept. 17, 1910.

WILLIAMS, L. L., surgeon. Granted seven days' leave of absence from Sept. 19, 1910, under paragraph 189, Service Regulations.

MCINTOSH, W. P., surgeon. Granted seven days' leave of absence from Sept. 23, 1910.

PARKER, H. B., passed assistant surgeon. Granted three days' leave of absence from Aug. 25, 1910, on account of sickness.

ANDERSON, JOHN F., passed assistant surgeon. Directed to proceed to Ellis Island, N. Y., upon special temporary duty. Sept. 16, 1910.

GOLDBERGER, JOSEPH, passed assistant surgeon. Granted one month's leave of absence from Sept. 26, 1910.

SCHERESCHEWSKY, J. W., passed assistant surgeon. Directed to report at Bureau upon special temporary duty. Sept. 16, 1010.

FRANCIS, EDWARD, passed assistant surgeon. Directed to proceed to Philadelphia, Pa., New York, N. Y., and Detroit, Mich., upon special temporary duty. Sept. 14, 1910.

MCCOY, GEORGE W., passed assistant surgeon. Directed to proceed to Berkeley, Cal., upon special temporary duty. Sept. 14, 1910.

WARREN, B. S., passed assistant surgeon. Detail to represent the service at the meeting of the state health officers, to be held in Waterloo, Ia., Sept. 20, 1910. Sept. 15, 1910.

RUCKER, WILLIAM C., passed assistant surgeon. Leave of absence for one year without pay from June 4, 1910, amended to read from June 4 to September 14, 1910, without pay. Granted ten days' leave of absence from Sept. 14, 1910.

STANTON, J. G., acting assistant surgeon. Granted twenty-six days' leave of absence from Sept. 21, 1910.

CURLEY, C. P., acting assistant surgeon. Granted twenty-one days' leave of absence from Sept. 22, 1910.

MAGUIRE, E. S., pharmacist. Leave of absence for thirty days from Aug. 6, 1910, amended to read twenty days from Aug. 6, 1910.

BECK, J. E., pharmacist. Granted thirty days' leave of absence from Sept. 15, 1910.

BELL, J. M., pharmacist. Relieved from duty at Chicago, Ill., and directed to proceed to Savannah (Quarantine), Ga., and report to the medical officer in command for duty and assignment to quarters. Sept. 16, 1910.

STUMP, F. A., pharmacist. Directed to proceed to Honolulu, Hawaii, and report to the chief quarantine officer for duty. Sept. 12, 1910.

PROMOTION.

OTT, C. R., pharmacist. Promoted to pharmacist of the second class, to date from Aug. 29, 1910.

BOARDS CONVENED.

Board of medical officers convened to meet at the Marine Hospital, San Francisco, Cal., Sept. 26, 1910, for the examination of Assistant Surgeon Friench Simpson, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the board: Surgeon Rupert Blue, chairman; Passed Assistant Surgeon F. E. Trotter; Passed Assistant Surgeon R. E. Ebersole, recorder. Sept. 14, 1910.

Board of medical officers convened to meet at the Marine Hospital, Stapleton, N. Y., Sept. 26, 1910, for the examination of Assistant Surgeon R. A. Herring, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the board: Surgeon Hiram W. Austin, chairman; Passed Assistant Surgeon W. A. Korn; Passed Assistant Surgeon George L. Collins, recorder. Sept. 14, 1910.

Board of medical officers convened to meet at Philadelphia, Pa., Sept. 21, 1910, for the purpose of determining the physical condition of Surgeon Eugene Wasdin. Detail for the board: Surgeon Hiram W. Austin, chairman; Surgeon W. G. Stimpson, recorder. Sept. 15, 1910.

A CORRECTION.

IN our issue of Sept. 29 the note entitled "The Cost of Progress" should have been credited to the *British Medical Journal*.

RECENT DEATHS.

COLLINS, ORVILLE WILLIAMS, M.D., M.M.S.S., died in South Framingham, Sept. 5, 1910, aged fifty-seven years.

DR. WILLIAM COWPE GARDNER, of New York, died on Sept. 29, from cardiac disease. He was born in Liverpool, England, in 1855, and was graduated from the Long Island College Hospital, Brooklyn, in 1892.

Dr. JOHN ERHARD, of College Point, Borough of Queens, New York City, died on Sept. 28, at the age of forty-eight years. He was graduated from the Long Island College Hospital in 1896.

DR. HUBERT B. GUDGER, of Asheville, N. C., died in New York City on Oct. 2, at the age of twenty-six. He graduated from the University of Pennsylvania Medical School in June, 1910.

DR. CHARLES EDWIN MILES, who died last week in Roxbury, was born at Stow, Mass., on Dec. 31, 1830. He graduated from Worcester Medical College in 1859, and since that time had practised medicine in Roxbury. He was at one time chairman of the Massachusetts State Board of Registration in Medicine. He is survived by his widow.

ACUTE THORACIC EMPYEMA. AVOIDANCE OF CHRONIC EMPYEMA. RIB TREPHINING FOR SUCTION DRAINAGE.*

BY SAMUEL ROBINSON, M.D.,

Surgeon to Out-Patients, Massachusetts General Hospital; Visiting Surgeon to the Harvard Clinic.

DEATH of patients as a penalty for neglect of diagnosis and treatment of inflammations within the abdomen has finally persuaded us to recognize such conditions early. Surgeons, realizing the danger to life, operate promptly to remove infection, or with close observation seek to limit the spread of the disease. Suppurative infections of the thorax are regarded with less respect, and are looked upon with reason as less threatening to life; hence the lax enthusiasm to recognize promptly thoracic infections, and a tardiness approaching indifference on the part of the surgeon in securing drainage. In other words, in suppurating conditions of the lung and pleura, as in other lesions of the body, the effort made is in direct proportion to the fear of losing the patient. A not uncommon remark is the following: "I have never lost a case of empyema."

The object of this paper is to emphasize the fact that while nature strenuously combats pleural infections in spite of our incomplete efforts, accuracy of diagnosis, prompt surgery and diligent after-treatment of such conditions are absolutely necessary not only to save the patient, but to shorten the convalescence, to prevent amyloid disease of other organs and to restore the normal function of the lung and pleura. Complete recovery and not the mere saving of life should be, from the outset, the main object in the treatment of thoracic suppuration. It cannot be denied that abscess of the periphery of the lung, if early recognized and operated upon, might avoid a local empyema. Local empyema detected with like promptness will often prevent the occurrence of a general pleural infection, and, furthermore, chronic empyema is a condition which should never exist, and which is in each and every case attributable to neglect either in the recognition of infection at its early stages, in its operative treatment or in its post-operative management. A large percentage of the cases of purulent pleurisy which result after operation in so-called chronic empyema, namely, in the existence of a large thick-walled cavity, with many ounces of residual pus contents, are due to the negligence of the internist. A smaller group of cases of chronic empyema may be credited to the neglect of the surgeon to provide for the re-expansion of the lung after complete or incomplete drainage; and while the main discussion of this paper will deal with the prevention of chronic empyema by methods of thorough drainage and efforts at re-expansion, it should be noted by the internist that such re-expansion is frequently impossible when he has allowed a purulent pleurisy to remain unrecognized or neglected until the lung is so adherent in its retracted, compressed condition that expansion is impossible without a grave radical procedure, even though the expansibility of the lung tissue may yet persist.

Through the courtesy of the Visiting Staff of the Massachusetts General Hospital, I have had the opportunity to operate upon fifty-one patients with intrathoracic diseases, of which thirty-four cases were empyema. The views expressed in this paper are based essentially upon experiences with these cases, although a detailed account is omitted.

DIAGNOSIS.

I hesitate to discuss the diagnosis and differential diagnosis of a condition so well-known as purulent pleurisy, but my attention has been called to the difficulty which attends the diagnosis and localization in certain cases. Earlier diagnosis would be favored if we were as keenly on the lookout for suppuration in the thorax as we are in the abdomen. No case of pneumonia should be regarded as properly treated when in the process of resolution one is not constantly watching the temperature, physical signs and leucocytosis for the possible accumulation of serous or purulent fluid. There is no doubt that empyema is more often diagnosed as resolving pneumonia than that the signs of the resolving lobe are mistaken for pus. To doubt the ability of the average doctor to detect fluid in the thorax would be an attack upon the fundamentals of his training, and it is more reasonable to doubt his persistence in searching for a focus to explain a rise in temperature, an increased leucocytosis, a chill or night sweat, vomiting, abdominal pain or other latent symptoms in the convalescence following the crisis of pneumonia. Though convinced that pus is present in the chest, we are often guilty of lack of diligence in its pursuit. Flatness in place of dullness, absence of râles, an absent or much diminished respiratory note, should aid in differentiating a pyothorax from an area of consolidation. Localized tenderness to pressure on the thoracic wall (Musser) may aid in diagnosis, but whether certain or in doubt as to the presence of pus, exploratory thoracentesis should be done in every case, not only to convince the internist of its presence, but to guide the operator in his thoracotomy. Such diagnostic punctures are, to be sure, frequently negative, even after repeated effort. Granted sufficient persistence, I have never known this method to fail in positive cases except when the pus was between the diaphragm and the under surface of the lower lobe, or encapsulated between the pleural surfaces of an interlobar fissure.

Needle diagnosis is often neglected for one of two reasons. There may be no suitable needle within easy access, or it is in no condition for use. Some practitioners hesitate to employ a needle puncture, either doubting their ability or dreading to suggest a semi-operative procedure to the septic patient and discouraged relatives. No surgical procedure impresses me as more brutal that the *stabbing* method of thoracentesis. Even with a

* Rib-trephining was suggested to me by Dr. Hugh Cabot, who states that the method has been employed by a Norwegian (written in connection with Dalton Scholarship, 1910-11), whose name he does not recall. In an extensive review of the literature I find no reference to this subject.

preliminary incision in the skin, with or without ethyl chloride, the needle is jabbed through the sensitive soft parts, including the parietal pleura, and, even in the hands of the expert, not infrequently pierces the lung. The procedure is distressing to the patient, and this fact alone may deter one from employing a second, third or fourth puncture when the first is negative. In a series of thirty-five thoracenteses performed on phthisis patients for the establishment of nitrogen artificial pneumothorax, I have succeeded in avoiding discomfort to the patient by a method which should be more generally employed. After freezing the skin with ethyl chloride, a ½% solution of cocaine is injected in the skin covering a area of ½ cm. Through this the hypodermic needle is inserted perpendicularly, the solution being forced gradually ahead of the needle as it passes through the layers of the chest wall. In the resulting absence of sensitiveness, the upper border of the rib below can be carefully made out, and more of the solution forced through the intercostal muscles against the sensitive pleura, which absorbs the cocaine slowly from the adjacent tissues. Puncture of the pleura then causes no pain. If the hypodermic needle is not used for aspiration, an aspirating needle can be inserted through the same channel with no discomfort. If aspiration is negative, by this anesthetic method of thoracentesis the usual fear of the patient of another *stab* is avoided, and the persistence of the operator to search further is not discouraged. If abscess of the lung has been excluded by the absence of sputum, as is invariably justifiable, and the presence of pus is still suspected, it is fair to presume after a series of negative punctures in the suspected areas that the pus is encapsulated in a fissure, or on the diaphragmatic surface. In three of my cases pus was found at operation in this latter situation and occupied the costo-diaphragmatic angle, which in the stabbing method is avoided for fear of injury to the diaphragm and opening of the abdomen. I have found more than a pint of pus retained in this angle at a point below the usual safe limit of exploratory needle puncture, namely, the eighth intercostal space. Experience has shown me that, by the cautious method above described, the diaphragmatic angle may also be explored in its entire circumference. The last case of this kind upon which I operated had survived six negative needle punctures. These discouraging results, in spite of continued leucocytosis and night temperature, resulted in a delay of eight weeks, as a result of which the pus increased over the diaphragm and forced the lung upwards, holding it there until its firm adhesions were formed. At operation an exploratory resection of two ribs was made at the safe level, where the pleural layers were found adherent. Separating them with the examining finger in a downward direction eventually permitted the escape of pus, although a new drainage point had to be established in the costo-diaphragmatic angle, evacuating a liter of pus. Convalescence of the patient has been unsatisfactory, and a large cavity corresponding to the volume of the pus still persists; in other words, a chronic empyema has developed as the result of the eight weeks' delay which will later necessitate a thoracoplasty for its obliteration.

Doubt frequently arises in the convalescence of pneumonia as to whether suppuration exists in the form of an abscess or of empyema. The presence of sputum in small or large quantities should be the main guide. Pure empyemata are ordinarily purulent pleuresies in which the infection has traversed the lymphatics through the basement membrane of the visceral pleura, and a sputum is rarely present. If, on the contrary, in the resolution of pneumonia an abscess has developed near the periphery of the lung, the visceral and parietal pleuræ may become adherent. The physical signs when the abscess cavity is full are those of localized empyema, and if the abscess is connected with a bronchus, and a purulent sputum is present, and if, furthermore, the exploratory needle, without going to any apparent depth, draws pus, the case is regarded as one of "empyema which has broken into a bronchus." I am yet to be convinced that a true empyema often finds its way through the visceral pleura and thence into a bronchus. The reverse, on the contrary, is often true.

The previously existing abscess has, through protective adhesions, obliterated the pleural space and thus prevented an empyema; and, being unable to find an exit through the chest wall, has broken centrally into a bronchus. Cases are reported of spontaneous cure of empyema by rupture into a bronchus. The considerable evacuation of sputum which gives rise to such conclusions can only escape through bronchial branches of a considerable diameter. Such are not found at the periphery of the lung. In other words, if a true purulent pleurisy of lymphatic origin reaches a large bronchus, it must first produce an abscess of the lung, which in turn perforates the wall of a bronchus. Who can deny that the abscess occurred previously, that the local or true empyema followed by extension of the abscess to the periphery, with adhesions to wall it off, or a direct rupture into the unprotected pleural cavity? The abscess, however, continues its parenchymatous necrosis, and a bronchus is entered. The clinician may have failed to note the pre-existing abscess and, having later discovered signs of empyema, concludes at the time of rupture that the empyema has burrowed into the lung. Autopsies frequently reveal necrotic lung tissue connecting with a bronchus and also with a pleural empyema, but I see in such post-mortems no evidence as to whether the abscess or the empyema was primary in origin. Morison states that interlobar empyema is the variety which most commonly ruptures into a brouchus. The two cases of interlobar empyema which I have seen at autopsy were both accompanied by adjacent abscesses of the lung. Of three cases of so-called localized empyema upon which I have operated, there was necrotic lung tissue at the base of the cavity and twice with a bronchial connection. It is

conceivable, therefore, that the terms "localized" and "interlobar empyema" are often misnomata. Adhering to the definition of empyema, "pus within a cavity," the term should only be applied when two layers of pleura, either visceral and parietal, or two visceral layers form the opposing boundaries of the cavity. If thoracotomy is done for localized empyemata, and lung parenchyma is at the pulmonary side of the cavity, it is evidence that the visceral and parietal pleuræ are adherent as one layer incised in the thoracotomy. The condition is really one of abscess of the lung. If the inner wall of the cavity, on the contrary, presents visceral pleura with a fistulous opening to the lung, the condition is justly called a localized empyema secondary to abscess of the lung. It is this latter condition which is often unrecognized and which when undrained exteriorly may lead to rupture into the bronchus. Localized empyemata on the lateral walls of the chest are more commonly pure peripheral lung abscesses or restricted empyemata connecting with and secondary to an abscess. Those at the base of the pleural cavity are generally true empyemata limited by adhesions.

We have considered purulent pleurisy which is associated with pneumonia to emphasize its frequency as a sequel to this disease, but its diversity of origin must not be overlooked. Another group of empyemata is that which is associated with inflammatory conditions beneath the diaphragm which by lymphatic extension involve the diaphragmatic pleura and the adjacent visceral layer of the lower lobe. Abscess of the liver, subdiaphragmatic abscess and perforated duodenal ulcers not infrequently lead to this condition with or without perforation of the diaphragm, and the attention of the physician is distracted from the pleural involvement and the necessity of drainage by his anxiety concerning the abdominal conditions.

Infections of the pleura by blood metastasis are sometimes seen in scarlet fever, measles, typhoid and whooping-cough and other systemic infection. A careful chest examination should be made when the progress of these diseases is accompanied by signs of additional septic absorption. Trauma and local disease of the chest wall as causes of pneumonia are less often overlooked because of the direct association of the pleura with such conditions. I am convinced that infection of a pleuritic effusion by needle puncture is of extremely rare occurrence, and should not be considered as among the probable causes of empyema. The fact that the first needle puncture withdraws a sterile fluid and a later puncture pus ordinarily indicates that the fluid has for other reasons in the meanwhile become purulent. When the withdrawn fluid of a primary puncture contains bacteria, the approach of empyema may be suspected. Martin even recommends the aspiration of such non-purulent infected effusions to anticipate the added difficulties of a subsequent empyema. Griffiths, on the contrary, found but two of one hundred and fifty-one cases of aspiration in which the fluid became purulent, one of which was complicated with tuberculosis and the other with erysipelas.

In a series of ten cases of bronchiectasis which have come under my observation, two had been previously diagnosed as empyema. There is no real excuse for this confusion. The chronicity of the usual case of bronchiectasis perhaps originating with influenzal pneumonia, with its exacerbations in the winter season simulating attacks of grippe, together with the presence of a definite and characteristic sputum containing influenza bacilli, should persuade the diagnostician to give less regard to the local signs usually present in the region of the lower lobe, which may somewhat resemble the signs of empyema.

A group of cases to which we have not referred is that in which a differential diagnosis between thoracic and abdominal involvement is often quite impossible. In such cases thoracic or abdominal breathing are often useful in determining whether the peritoneum or the pleura are involved. In a child recently seen at the Massachusetts General Hospital, both thoracic and abdominal symptoms were present. Abdominal pain had been present, and when appendical involvement was suspected, although the abdomen was not distended or rigid, and presented but a vague tenderness in the right half of the abdomen, the chest examination revealed slight dullness in the lower right chest, approaching flatness in the axillary line. The respiratory note was not clear, but the signs were so near the diaphragm that a diagnosis of pleural involvement was doubtful. I was sufficiently convinced that the chest signs were abnormal not to recommend a laparotomy. The latter was done, however, and although the appendix was normal, a small amount of thin sero-hemorraghic fluid was found in the peritoneal cavity. The child made a normal convalescence, and on the second day after operation the signs in the thorax were somewhat more marked. The surgeon who operated was guided to a great extent by the pure thoracic breathing. Although the pathological report of the fluid was negative, it is conceivable that this was an infection which involved both the pleura and peritoneum, and that the signs in the chest were due to a similar slight amount of fluid within the pleura. It should not be forgotten, however, that abdominal symptoms are frequent when purely secondary to pleural involvement. The abdominal breathing may be in such cases helpful at times, but I suspect that this symptom should be reserved as a late resort in doubtful cases and not as a pathognomonic indication.

The x-ray should be considered as a contributing means of diagnosis of purulent pleurisy. In a series of some seventy thoracic cases which I have followed, including bronchiectasis, empyema, abscess of the lung, pneumonia, malignant disease, syphilis and pneumothorax, I have come to believe that, as a means of differential diagnosis between purulent pleurisy and some other conditions, it is very unsatisfactory. If the empyema fluid is surrounded by pleura sufficiently thickened to cast a shadow, the extent or localization of the

empyema is not definite. If the pleura is thickened and an effusion is absent, a similar shadow is frequently seen in the plate. The shadow of a consolidated or resolving pneumonic process is frequently not unlike that produced by empyema fluid through the thickening of the pleura. The shadow of an interlobar empyema which is invariably associated with the thickening of the adjacent pleural layers again fails to aid in the localization of the septic material. The French method of slanting the rays in such a way as to throw the interlobar fissure into a linear shadow crossing the plate transversely is helpful in differential diagnosis, but with the usual anteroposterior direction of the rays the shadow of an interlobar empyema may be indistinguishable from an anterior or posterior localized empyema. It would seem, therefore, that the x-ray fails in those doubtful cases in which we need its help. The presence of pus can generally be demonstrated by a thoracentesis and other methods mentioned above, but in the differentiation between intrapulmonary and extrapulmonary pus, and between thickened pleura, fluid and pus, the radiograph may be very misleading. I have a group of plates from which one ignorant of the history and physical signs would be unable to differentiate between the various conditions which they were found to represent, and this because the shadows present were in most respects similar.

The history of the patient, in addition to the physical examination, should be the guide of the operator in determining the special form of treatment which is indicated, and it is important to decide what particular form of empyema is present before the most suitable procedure is determined. Frequently this decision is in doubt until pleurotomy has been performed.

BACTERIOLOGY.

I believe it to be a mistake to regard the bacteriology of purulent pleuritic effusions as an important factor in the selection of treatment. The fact that pure metapneumonic empyemas sometimes are cured spontaneously should be disregarded, and it would be well, furthermore, to forget that repeated aspirations of pneumococcus pus have also resulted in cure. Every unilateral empyema should be drained by an operation, whether the material obtained in diagnostic thoracentesis is pure pneumococcus, streptococcus, staphylococcus or the three combined. In reviewing the statistics of eight writers on the bacteriology of this subject, I am convinced that their conclusions regarding the relative frequency and virulency of the different infections are of interest in prognosis, but of no significance as regards treatment. Undoubtedly the pneumococcus infections are the most benign, but free drainage should nevertheless be employed. A streptococcus empyema secondary to streptococcus infection of the abdomen or elsewhere in the body is more virulent and more unfavorable in prognosis, but all forms of empyemata, regardless of their origin and bacteriology, should be recognized promptly and drained freely, re-expansion of the lung being the main purpose from the outset.

TREATMENT.

No better argument can be offered in behalf of early recognition of purulent pleurisy than the speedy recovery of most cases operated in the early stages. Patients so handled, though provided with inefficient drainage and lack of any kind of suction, frequently recover promptly for the reason that the lung is yet mobile, and can aid in the evacuation of residual pus. The literature on this subject abounds in reports of small groups of cases with uninterrupted recoveries of short duration, treated with or without particular methods of drainage or suction, and the recovery of such cases should be credited to their early recognition more than to the method of handling.

If a localized empyema or peripheral abscess is suspected and the combined methods of diagnosis intimate that the general pleural cavity is protected by adhesions, drainage and obliteration of the small cavity need alone be thought of. I prefer in such cases to resect a large enough area of ribs to enable free access to the cavity to stimulate growth of granulations or to suture in a skin and muscle flap to the base. If a true general empyema is present and promptly detected, as in the early stages of resolution of pneumonia, there is reason to believe that the lung not only retains its expansibility, but is not sufficiently adherent to prevent ready expansion. In such cases, it must be admitted that, with good drainage at the lowest possible point, prompt recoveries are common without artificial methods of expansion. I feel assured, on the contrary, that if such cases were drained with a tube and no dressing were applied covering the tube, in other words, were so handled that air could pass freely in and out of the chest, re-expansion of the lung would be impossible and that such a case would necessarily result in the permanent cavity formation—chronic empyema. If the diameter of the tube is equal to or greater than the diameter of the laryngeal opening, by the well-known principles of physiology the normal negative pressure within the thorax will be lost, and if atmospheric pressure exists within the chest, the normal elasticity of the lung in the absence of adhesions (which we assume in this group of cases) will result in its retraction. The explanation of the recovery in such cases without artificial suction, seen most commonly in children, rests in the fact that the drainage orifice is always covered with a pus-soaked mass of gauze which covers the opening more completely at inspiration, resulting in a partial negative pressure between the pleural layers which inflates the lung. All expiratory efforts with the glottis closed, as in coughing, produce a positive pressure within the lung of the unoperated chest, which, in turn, partially inflates the lung of the diseased side, at the same time forcing intrapleural air out of the drainage opening. When the latter is partially or completely closed at the next inspiration, the lung is more and more expanded, until adhesions

form in the expanded condition, thus gradually obliterating the pleural cavity, from which by the same process the pus has slowly been evacuated.

Granting, then, what I regard as an indisputable fact, that all cases of acute empyema with a drainage opening of 1 cm. would result in partial retraction of the lung and the existence of a permanent cavity if the thoracotomy wound is not partially or completely closed at inspiration, we are forced to admit that either a valvular action must be provided at the point of drainage, or actual suction applied. Many operators who disclaim the necessity of artificial suction are unmindful of the fact that in all of their cases the normal suction effect of the expansion of the chest wall has been preserved to a greater or less degree by the mere application of a gauze dressing to the drainage orifice. Some surgeons, including Cabot and Schede, recognizing the impossibility of utilizing chest wall suction and not relying upon the valvular action of the gauze dressing, have employed mackintosh or rubber bandages outside the gauze to make secure the air-tight closure of the opening at the time of inspiration. Despite the efficiency of gauze alone with a firm swathe in a certain number of cases, I believe that every case of acute empyema, though recognized early, should have at least this artificial support to the suction power of the chest wall.

A second group of empyema cases are those in which the acute stage has been neglected and the pus allowed to remain undrained for a longer period of time. Such cases may have a large accumulation of pus, and are ordinarily provided with free drainage, and the surgeon, conscious of his many successes with earlier cases without artificial suction, applies the usual gauze and binder dressing which, though constantly soaked with pus, does not aid in the re-expansion of the lung, and a chronic pus cavity results. Cases of this group are constantly being discharged from hospital wards to local physicians, the surgeons often remaining blissfully ignorant of the prolonged convalescence and necessity of further operation which frequently attend such cases.

To this group of cases belong those which may have been promptly recognized but insufficiently drained. It is the general practitioner and not the surgeon who is usually responsible for cases which come to further operation after a preliminary but incomplete drainage by the local physician. By this I mean that the drainage point selected has been too high to empty the cavity, and perhaps too small to allow the free escape of pus and fibrin. Frequently, too, an intercostal incision has been made without the introduction of a permanent trocar or tube, which incision often closes before the drainage is complete. In this way an acute, early detected empyema may be converted into our second group, and the lung, although originally non-adherent and expansible, has become adherent and is approaching the chronic form. Through the history and duration of the case information may thus be obtained as to which group of cases is to be dealt with by the operator. When this point remains yet in doubt, a conclusion should always be arrived at by introducing the finger into the thoracotomy wound to see if the lung is palpable. If, as is usually the case in early cases, the lung is felt touching the finger at inspiration or in gagging or coughing under light anesthesia, it may be assumed that the lung is not firmly adherent in a retracted condition. If, on the contrary, the lung is not felt when the examining finger plugs the chest wall opening, it is conclusive evidence that the lung is prevented from expanding and that simple methods of aiding the chest-wall suction must be supplanted by artificial suction and breathing exercises in the attempt to force the lung to its normal position. In the above different conditions I find the explanations of the much-disputed question as to why the lung can sometimes be felt partially refilling the pleural cavity as the pus escapes, and why the lung remains out of reach. It must not be forgotten that the size of the opening makes a difference in this digital exploration. If air can pass the examining finger freely, negative pressure at inspiration is practically lost and there is no force acting to re-expand the lung. In a recent discussion one surgeon took the view that the lung could always be felt "coming down" towards the opening. Another replied that he had not had this experience. These different views raise the question of how long had the pus been present before operation; did the examining finger plug the opening; and was there any source of inflation from the opposite lung by closure of the glottis in the spasms of light anesthesia?

If the history and digital examination prove a definite failure to re-expand, a curved instrument, such as a uterine sound, should be inserted to establish the position of the retracted lung, and to determine the extent of the cavity. Drainage adequate both as to size and position of opening is then of first importance. If the examination reveals that the bottom of the cavity is more than an inch below the level of the first opening, a second should be made at a dependent point guided by the examining finger within the thorax. Drainage from two openings may thus be obtained, or the upper one may be closed, though infection in the latter is likely to occur. I am not in sympathy with Fowler, who states that adhesions may occur in the costodiaphragmatic angle raising the level of the bottom of the cavity so that the drainage need not be at the lowest point. This advice is dangerous and more harm has been done by high drainage and the persistence of residual pus below the opening than by low drainage which may become occluded by adhesions.

When thus confronted with one of this group of cases in which the lung fails to re-expand, the nature of the difficulty should at this time be determined. If the duration of the disease and neglect of drainage have not been sufficient to classify the case as one of chronic empyema, and if exploration of the cavity indicates that the lung has not lost its expansibility and may not be permanently adherent, the indication is to remove the septic material. A second and equally important indication is the effort to encourage the

re-expansion of the lung. In certain cases the latter will be successful, while in others it may fail, but before concluding that the case must come to further operation for freeing the lung or obliterating the cavity, the patient should at least have the benefit of the doubt. If it is evident from the outset that artificial suction would be of no avail, the indication is drainage with a resection of ribs too great to permit of suction, but free enough to prevent the accumulation of a residual pus and to allow free introduction of large tubes, gauze and instruments by which the whole cavity may be cleansed. Such procedure is but preparatory for later operations which cannot be discussed in this paper on acute empyema; but whether these future operations be decortication of the visceral and parietal pleuræ to enable expansion of the lung, or extensive thoracoplastic operations to cave in the chest wall, or the Beck treatment by bismuth and vaseline injections, a free opening is essential to a sterilization of the cavity and a means of escape for an excess of bismuth in the Beck treatment. Such open evacuation results in a marked improvement in the patient's condition and resistance for further proceedings. But this very method of handling this group of cases to which chronic empyemas strictly belong is, alas, too often employed in our second group, which are by no means beyond the possibility of re-expansion by methods of artificial suction. To such treatment we shall now refer.

We have advocated in the early cases of the first group a persevering maintenance of the suction provided by the chest wall which is at least partially accomplished by a gauze dressing and a binder and better by the mackintosh dressing. These pseudo-suction methods are only advocated in those instances where better facilities for suction are not at hand. If the case is suitable for the use of negative pressure, and any suction device is available, its utilization is the best treatment.

Methods of suction which leak are the predominant ones in hospital clinics, but are better than no suction at all, such as is seen in the use of a spool drainage tube covered with a frequently renewed light gauze dressing and a loose cheesecloth swathe. One can often hear air rush in and out of the tube during the respiratory movements, and except in cases which we have classified in our group of chronic empyemas awaiting further operation, this sound is evidence of neglect.

The method of Buelau is an instance of a definite effort towards re-expansion. A certain amount of negative pressure is undoubtedly maintained by this method. The intercostal introduction of a large trocar which is replaced by a close-fitting tube is open to criticism because of the small caliber of the trocar which could be introduced between the ribs of certain cases. He furthermore depends entirely upon siphonage or suction by immersing the long pus-filled drainage tube in a basin of antiseptic solution on the floor. Although no actual suction is employed except the weight of the pus columns, air certainly cannot enter the thorax at inspiration, provided the tube connection with the chest wall is air-tight. A prevalent and justifiable opposition has developed against intercostal drainage of empyema, but if done by Buelau's trocar method it is less open to attack than when a simple intercostal incision is made and a tube carelessly inserted. Such drainage invariably results in leakage around the tube which renders the suction less adequate. It must be admitted that the tissues punctured by a large trocar, for the very reason that they tend to prevent leakage, at the same time tend to compress the tube. It is a simple method with some advantages, and must at least at the outset favor drainage and re-expansion.

The method of Perthes has attracted much attention and is commonly used in European clinics. Three to 5 cm. of one rib are resected, a rubber tube supplied with a collar is inserted, the region of the wound around the opening is smeared with lanoline to favor the adhesion of the collar to the skin, and wide flannel strips stitched to an occlusive dressing of rubber membrane are brought around the thorax. Lenhartz has favored the adhesion of the collar by sticking it down with gauze and collodion. A more rational method of rendering the thoracotomy air-tight is that of Cotton of cementing a rubber collar to the skin with gutta-percha paste. Perthes, in addition to abandoning the intercostal method of Buelau, is not satisfied with siphon drainage, but employs actual suction by means of a Bunsen air-pump. Perthes, by rib-resection and larger wound, sacrifices the tendency of the tissues to hug the drainage tube, as in Buelau's method, necessitating a somewhat complicated technic of applying an air-tight collar to hermetically seal the edges of the opening, nevertheless is able to introduce a larger tube which is undoubtedly more efficient in removing fibrin and lymph accumulations. Operators in this country who are convinced of the necessity of some method of artificial suction frequently excise a rib, insert an ordinary tube or spool, stitch the skin and muscle close to the drain, and attach some sucking device, such as a Politzer bag or a series of water-bottles for hydrostatic suction. But those who have followed the convalescence of cases so treated will doubtless agree that from a mechanical standpoint, to say nothing of surgical results, these methods have failed. I venture to suggest that the cases so treated which have not resulted in permanent cavities, and doubtless there have been many, were cases which would have resulted in drainage and re-expansion by the gauze and binder dressing. In other words, the apparatus has been given the credit of the cure when its mechanical action has usually been worthless.

We have not mentioned a method of valvular closure of the drainage tube at the time of inspiration. It should be borne in mind that all methods which we have considered are supposed at least to accomplish inspiratory closure, although the tube remains patent; but the resistance of the suction or siphon negative pressure being greater than the intrathoracic pressure, the end result is like unto the complete closure of the tube as in the valvular methods. Suction and siphonage,

however, continue during expiration aiding in the escape of pus, while in the valvular method gravity or forced expiration are alone depended upon to remove the fluid. Three English writers, Baylor, Hutton and Williams, have employed the valve idea. A gutta-percha nipple slit at the end and enclosed by a piece of glass tubing is employed by Hutton. Williams uses a rubber valve such as may be obtained from the air-bag of an ordinary spray-producer. Baylor employs a rubber valve enclosed within a metal casing.

Thiersch has simplified this valvular method by attaching to the Nélaton catheter, which is introduced between the ribs by the trocar method described by Buelau, a thin rubber tube which is easily collapsible by the negative intrathoracic pressure which is produced at inspiration.

To recapitulate, these and innumerable other devices have been employed in the drainage of empyema, all of them embodying one of three principles, — siphonage, suction and valvular action. Intercostal trocar puncture, and rib-resection "with or without" the use of a rubber collar, constitute the two main divisions in the method of thoracotomy.

In scrutinizing the various methods of siphon and suction drainage, some of which we have mentioned, it is evident that the key to the situation is the amount of leakage which may occur outside of the thoracotomy wound. Leakage elsewhere in the apparatus will also lead to unsatisfactory results, but we may presume that the usual point of leakage is around the drainage tube, a condition which I have repeatedly seen in different methods employed, and which doubtless occurs at the end of a greater or less period of time in all methods of drainage. Statistics given by the advocates of siphon drainage with a trocar puncture show that leakage may begin to occur within a week, necessitating the removal of the tube and its replacement by a larger one to fill the gap in the tissues which has resulted from the prolonged presence of a foreign body. *The permanency of the air-tight closure is undeniably the crux of the situation.* It is well known to those who have performed rib-rescetion and introduced tubes protected by rubber collars, rubber dam, adhesive plaster, lanoline, zinc ointment, gutta-percha, cement and other agents, that leakage is of frequent occurrence and that at best it can only be prevented by the most painstaking and continuous effort. The personality of the patient frequently determines the success. In a restless individual it is often impossible to maintain the intercostal tube or the larger tube through resected openings with their protective devices.

RIB-TREPHINING; A NEW METHOD.

The importance of maintaining air-tight suction leads me to advocate a method of rib-trephining, which I have employed in cases belonging to the first and second groups to which we have referred with greater success than with any of the other methods. When first employing this treatment, after trephining the rib I inserted a rubber tube selected to fit as tightly as possible, holding it in position by adhesive plaster and safety-pin or with a stitch through the skin. This prevented leakage for a number of days and was a great improvement on all other methods which I have employed. Even this leaked too early, and to prolong the period of air-tight closure I substituted a metal tube with a thread cut on one end and corrugated for the attachment of rubber tubing on the other. (Fig. 4.) These tubes are made in different sizes and of different lengths to suit the individual case, depending on the size of the rib and the depth of the chest wall tissues to be traversed. The less the tube projects beyond the skin, the better, as it receives better support by the soft tissues and the skin. It is not necessary to allow the corrugated portion to project beyond the skin sufficiently to support the end of the rubber tubing, for this may be applied to a depth within the soft tissues before the latter are sutured around it.

The position of the patient on the operating table has been the subject of considerable dispute. It is, of course, important that position should limit the excursion of the unoperated chest as little as possible. If, however, it is impossible to employ this position and at the same time have good exposure of the point selected for drainage, freedom of expansion of the unoperated lung should be sacrificed to good exposure. Operators have described cases in which they believed that death or collapse occurred because of the cramped condition of the sound side. I am of the opinion that the accidents in these cases have not been due to this fact, but rather to the method of anesthesia, or to the sudden introduction of air into the operated thorax. This sudden production of pneumothorax may cause no symptoms provided adhesions prevent the complete collapse of the lung. In most cases of purulent pleurisy, adhesions exist and the mediastinal pleura is thickened, rendering the mediastinum less prone to the oscillations which occur under normal conditions and which I have previously described.[1] A normal mediastinum may, following a sudden pneumothorax, bulge to the sound side at inspiration, thus restricting the expansion of the healthy lung. At expiration it may deviate to the opened side and retain an excess of residual air. Symptoms of dyspnea or collapse may thus come on in certain early cases of empyema, and although such cases are extremely rare, owing to the usual adhesions, it is conceivable that this rather than the cramping of the unoperated side during an empyema operation may explain the above fatalities.

As a safeguard against the ill-effects of sudden pneumothorax in patients susceptible to it, differential pressure may be used. In this series of thirty-four empyema operations I have employed a positive pressure cabinet in three cases and have always had apparatus at hand to use if necessary. When apparatus is not available for facilitating the work of the unoperated lung, and symptoms occur, the thoracotomy wound should be closed at the end of expiration with the hand

[1] "Experimental Surgery of the Lungs," Ann. Surg., February, 1908. "Surgery of the Lungs under Positive and Negative Pressure," Surg., Gynec. and Obstet., March, 1909.

or finger until a suction device can be applied. As will be seen later, the possibility of this pneumothorax accident is obviated by the rib-trephining method.

In a series of one hundred and fifty thoracic operations on animals in which for one reason or another the function of one lung has been seriously impaired, I have taken great pains to lay the convalescing animal on the operated side to enable the free expansion of the remaining lung. To my surprise the animals have generally rolled over to the opposite position when sufficiently recovered from their anesthesia, and have frequently lain upon the sound side from preference. I have operated on many thoracic cases in the human in which I have disregarded the sound chest by placing the patient in a lateral or even semi-prone position in order to have free access to the operative field, and with the intelligently applied anesthesia by Dr. Freeman Allen I have never seen dyspnea or cyanosis such as would occur if the unoperated lung were not functionating sufficiently for oxygenation of the blood. Doubtless a combination of ready accessibility of the operative field and an unrestricted attitude of the opposite chest is to be desired. Fig. 1 illustrates the position which I am in the habit of using with an ordinary operating table when no special table for thoracic surgery is available. The head of the table is raised both to favor respiratory function and to prevent the regurgitation of sputum. Inasmuch as the point of attack is ordinarily posterior to the anterior axillary line, the straight dorsal position hampers the operator. The patient is first placed in a lateral position, the lower buttock resting upon transversed sand-bag which is kept from sliding by tapes attached to the head of the table. While in this position the second long sand-bag is placed against the inclining portion and the patient allowed to fall back in a semidorsal position. Efforts to obtain this position by the use of rolled sheets and blankets are futile, and within a short time the patient's position is no longer the one desired.

ANESTHESIA.

General anesthesia is indicated in nervous patients unsuited for local anesthesia, but should, I believe, be avoided in most cases. When general anesthesia is indicated, the skilled anesthetist will choose that which seems the best suited to the particular patient. Nitrous oxide and oxygen I do not consider appropriate in thoracic conditions because of the tendency to cyanosis, which may be misleading, and because the already restricted air-supply should not be further reduced. Dr. Allen has convinced me of the success of the preliminary use of anesthol followed by ether and perhaps interrupted with chloroform. Under this selective anesthesia, with the concurrent use of oxygen applied to the end of the ether cone, in a series of thoracic operations I have not noted the least unfavorable symptom, thanks to its intelligent application by a skilled anesthetist.

Although general anesthesia when it is not abused rarely complicates the prognosis in empyema cases, local anesthesia is the methd of election. Cocaine can rarely be used in such operations even in mild solutions without causing some evidences of toxic absorption, and for this reason I prefer novocaine. The rib-trephining operation is especially adapted for local anesthesia as described below.

In selecting the point of drainage, no definite rules can be laid down, especially when limited areas of purulent pleurisy are to be drained. If, on the contrary, the empyema appears to be a general one, the drainage should be established at the point best adapted to the upright and not to the recumbent position. Thus the posterior or even the anterior axillary is preferable to the scapular line, provided the opening is made at the lowest possible point in the region of the costo-diaphragmatic angle. The eight rib in the posterior axillary line is a safe point, but the same rib in the scapular line is too high and may be encroached upon by the lower angle of the scapula, causing great inconvenience in the maintenance of tube or the changing of dressings. The region of scapula should never be selected in the rib-trephining method, inasmuch as the metal tube may be pressed upon accidentally or dislodged.

TECHNIC.

The skin is anesthetized, incised for two inches over the selected rib, dissection is then carried on under further local anesthesia. With gentle retraction of the edges of the wound a novocaine compress is applied to the periosteum with pressure for at least thirty seconds; this can then be scraped away for a length of 2 cm. without causing pain. A cranial trephine of the exact outside diameter of the tube to be inserted is then applied directly over the center of the rib (Fig. 3). Care should be taken to leave a bridge of rib at least 3 mm. in width above and below the trephine opening. In one case I neglected this and a fracture of the rib with dislodgment of the tube resulted. No pain is experienced by the cutting of the trephine until the posterior periosteum is reached. If pressure on the rib causes pain, it is because the empyematous area in that region with its concurrent pleurisy is in itself tender to pressure, as it is often found to be even by percussion. When this is the case, the rib may be supported by counter-traction; but with a sharp trephine gently applied the button may be removed with very slight pressure on the rib. When it is evident that the posterior periosteum is reached at any point in the trephine's circle, the needle should be inserted in the crack (Fig. 3) and the periosteum and over-sensitive pleura anesthetized, even if the solution is allowed to leak into the pleural cavity. Traction on the pleura caused by removal of the button is thus rendered painless, as is also exploratory puncture. After removing the button with mouse-tooth forceps, a Cabot trocar should be inserted into the pleural cavity to verify the selected point of drainage. This should be done with caution so that only a drop or two of pus escapes and does not come in contact with the superficial tissues. One of the metal tubes is then screwed

with the fingers into the trephine opening, and in spite of a lack of female thread the bone tissue is yielding enough to accept and hold the male thread, and for the last few turns the tube should be gripped with lion forceps. (Fig. 4.) It is quite surprising to find that the tube with its quarter-inch grip on the rib is held firmly and cannot be dislodged with the fingers. The muscles and skin, which should have been spared infection, are now sutured. A collodion dressing with a circular opening is then applied, and with the wound thus protected the complete opening of the pleura is indicated. This can best be done by the use of a pointed or blunt bistoury or a long-bladed scalpel, which is passed through the metal tube to the pleura. Great care should be taken to do more than merely incise the pleura, the knife being used for the purpose of excising a section of pleura the size of the tube. During this process, pus, of course, escapes freely, but runs directly into a basin and need not come in contact either with the skin or sterile sheet or even drench the floor. A rubber tube some six inches in length with a clamp at its outer end is then slipped over the corrugated portion of the metal tube and tied. No outside dressing or swathe is needed, and after sufficient removal of the pus contents at the time of operation the clamp is reapplied to the rubber tube and the patient sent to the ward.

It may be noted that by this procedure infection of the soft parts can and should be prevented, and that this avoidance of infection favors the tighter closure of the soft tissues around the tube, even when necrosis may commence within the rib.

An advantage of some importance which should be mentioned in this connection is that while pus is allowed to escape and aided in so doing by the subsequent methods of suction, air has at no time been allowed to enter the cavity. In other words, pneumothorax does not occur. In most of these cases the pus is under some tension, especially at expiration, and it will continue to fill the tube both at inspiration and expiration until the retained pus is no longer under pressure. For this reason it is advisable to discontinue the drainage of pus through the metal and rubber tube in the operating-room just as soon as its free flow is established, and before the tension is lost and air can enter at inspiration. The tube is clamped and the patient returned to bed, the clamp not being removed again until either siphon or suction drainage is established.

Having thus established an air-tight thoracotomy wound, a great effort should be made to avoid leakage in any part of the apparatus. In most forms of suction drainage a reservoir bottle is inserted between the tube leading to the chest and the suction device. This apparatus has failed because of leakage at this reservoir due to the fact that bottles with air-tight tube openings are not easy to procure. A common method is to bore two holes in a rubber cork wired into a wide-mouthed bottle, or to use a two-necked Wolff bottle with afferent and efferent tubes through air-tight corks. These forms of apparatus are habitually unsatisfactory in a hospital clinic, and in my cases I have substituted a piece of glass tubing two inches in diameter and ten inches long tapered to nipples at either end over which rubber tubing may be slipped. This device has the added convenience of keeping out of harm's way and of being applicable to ambulatory patients.

Having now two segments of the suction apparatus air-tight, any form of suction may be attached to the distal end of the reservoir. The choice of mechanism should depend upon the means at hand. If a water faucet is handy, a Bunsen air-pump as employed by Perthes is a steady and excellent means. A straight tube leading from the reservoir to a bottle of water on the floor can be attached producing a siphon suction. A small bivalve hand-pump, such as employed in aspirators, can be connected with the reservoir. With such a pump attached, sufficient negative pressure will be maintained within the reservoir to accomplish suction drainage. A small, noiseless, rotary air-pump can be likewise attached with electric connections to the lamp socket, providing a low but constant negative suction. Another commonly used suction device is a pair of bottles in which hydrostatic pressure is produced by allowing water to flow from one to the other, the two being at different levels. If the corks and tubes in such bottles are air-tight, the water will exert its suction but remains at a given level, thus avoiding the constant reversal of the bottles when one is filled and the other empty. If such bottles are used, the importance of their being hermetically sealed cannot be too strongly emphasized.

The shortest duration of convalescence which I have obtained by this method has been four weeks. In one case the tube remained fixed without leakage for three weeks, in which time the expected results will have been obtained. In the one fatal case thus treated in which death was due to an erysipelas infection two weeks after operation, an autopsy was obtained. The lung was found to be entirely re-expanded and adherent to the chest wall in its normal position. In this case previous to operation the chest was flat to percussion as high as the fourth behind and the third rib in front. Three pints of pus were evacuated at operation and during the two subsequent days. The air-tight suction has been sufficiently effective to withdraw through the tube clots of fibrin four inches long, and although occlusion of the tube may occur, there is less danger of it than in any other method.

CONCLUSIONS.

Cases of purulent pleurisy may be divided into three classes: Acute, subacute and chronic, the the first and second corresponding to the two groups which we have considered in this paper.

Suction or siphon drainage aid in the re-expansion of the lung in all cases of the first group; in most of the second; probably in none of the third.

Suction even though inefficient is better than no suction provided suction is constantly applied.

Prevention of leakage requires above all things

an air-tight thoracotomy wound. This is best obtained by the rib-trephining method with the application of a threaded metal tube.

The particular form of suction device applied to the air-tight wound will depend upon the means at hand.

SCOLIOSIS.

BY E. H. BRADFORD, M.D., AND ROBERT SOUTTER, M.D.

THE practitioner of medicine is in need of definite information as to the results to be obtained in the treatment of scoliosis, as well as to the best method of management of scoliotic cases. Textbooks instruct students; monographs, reports of investigations, aid specialists, but the practitioner needs to know what to advise a mother as to the management of the case of a daughter, afflicted with a crooked back, as to the expectation of benefit which can be offered and the necessary cost of treatment in time or money.

For practical purposes cases with curvature of the spine can be classed as: *First*, the weak backs; *second*, the curved backs; *third*, the twisted backs.

It is the latter class, or true scoliosis (i. e., spinal curve with structural change in cartilage, ligaments or bone), which is of special importance. The questions in regard to this class are:

(1) Whether a scoliotic case is likely to grow worse if untreated;

(2) Whether it is likely to grow better if untreated; and

(3) Whether the curve can be corrected under treatment.

In answer to these questions, it can be stated definitely that every case of true scoliosis, i. e., a twisted back in a young growing girl, is in danger of an increase of the deformity, the danger being in proportion to the extent of the existing deformity, the youth of the child, i. e., the num-

ber of growing years. The general condition of the patient is also a factor; the weaker the child, the greater the danger.

It can be said that the curve will not grow better if untreated. The superimposed weight of the head, arms and upper part of the trunk with structural changes of bone already established.

The nature of scoliosis has been accurately defined by Nicoladoni, and it may be well for the practitioner to bear in mind his definition: "Scoliosis is a deformity caused by excentric weighting

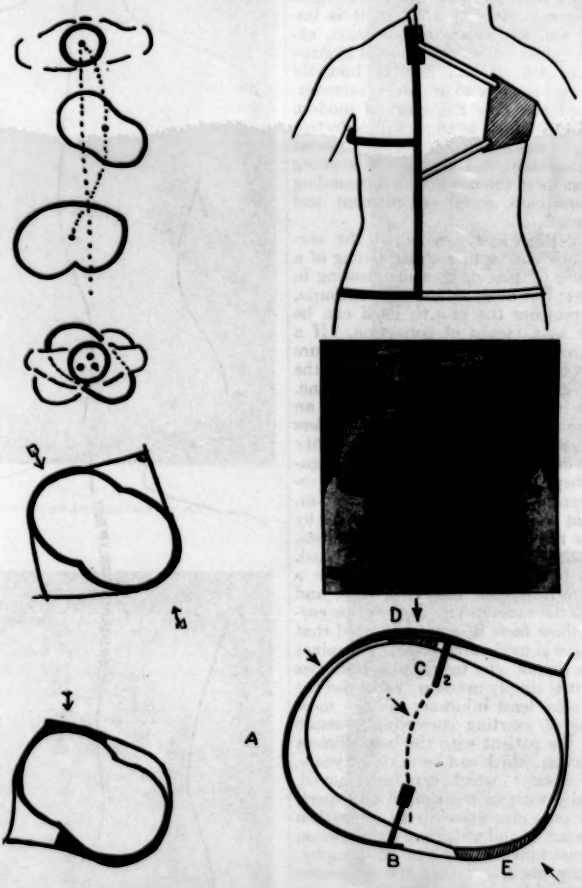

FIG. 1.
Illustrating points of pressure required for correction in an ordinary case of structural scoliosis.

presents always a force which tends to aggravate the deformity. The weight falls wrong, the spine being out of line, and it is difficult if a twist in the spine is present, and the patient is active, to prevent the superimposed weight from falling wrong.

The tendency to correct growth inherent in health may prevent an increase of the curve, but it is not sufficient to overcome a curve and twist of the spinal column; this leads to a twist as a result of the sides yielding or twisting, which consists of a movement in rotation of the individual vertebræ to the convexity of the curve. Finally, there is a distortion of bone structure, disarranging the arrangement of the vertebral planes horizontally, vertically and saggitally, and of the symmetrical shape of the vertebræ."

As Feiss has pointed out, there is, in addition

to the original influence which contorts, a distorting force from the patient's attempt to balance and hold the trunk in line.

In answer to the question whether cases of fixed curve can be successfully treated, many surgeons have been led by the complexity of the mechanical problem to regard scoliosis as not within the region of practical therapy, arguing that as it is impossible to control the necessary condition, expectancy and an observance of the laws of hygiene with gymnastics are all that can be honestly advised. Such an acceptance of defeat, however, is not in accordance with the spirit of modern surgery, nor with the facts as at present collected. It is evident, however, that proper treatment should be a consistent one during the growing years, and must meet the conditions surrounding each case, home care, social environment and financial resources.

Mr. Heather Bigg aptly compared the correction of scoliotic curves to a straightening of a curved cucumber by placing it while growing in a glass cylinder; as long as growth continues, under proper pressure the growth itself can be made to serve as a means of correction. If a young tree is growing crookedly and side pressure is applied, the tree becomes straighter, and the same may be regarded as true of a growing spine. Nor is stiffness in the curve to be regarded as an obstacle to correction, for professional tumblers and acrobats are able to increase the flexibility of the spine at desired points. Even some irregularity in the shape of growing bone cannot be regarded as preventing the possibility of correction. It is known that bone can be changed in shape by pressure, as the flat-headed Indians, and dentists, altering the shape of the jaw, have demonstrated. Experimenters have shown that by pressure a spinal curvature can be developed in dogs, and inferentially by the same means they can be corrected. From these facts it may be claimed that structural changes of moderate degree in the spines of growing girls do not offer insuperable obstacles to correction; it is simply necessary to devise the least objectionable, least injurious and the most effective means of exerting correcting pressure and furnishing the patient with the best efficient pressure apparatus; which can be worn for years, willingly if necessary; which can be removed, and applied daily without the skill of an expert; which permits muscular exercises to strengthen the shrunken muscles, and which will not imprison and weaken important muscles through atrophy. It is particularly important that the apparatus should not be unsightly or uncomfortable, for the factor of the patient's willing co-operation and good will are necessary in a treatment which needs to be carried on for a long time. The natural vanity of a young girl is needed as an aid rather than as an obstacle in treatment, which must be carried on with determination and persistency for years.

There are many appliances which are used for this purpose, of varying efficiency. The writer for the last few years has made use of one which seems to present some advantage. The nature of the appliance can be more readily seen by the illustrations than by any description.

The appliance is light and not at all disfiguring; it can be worn under the clothes, and the amount

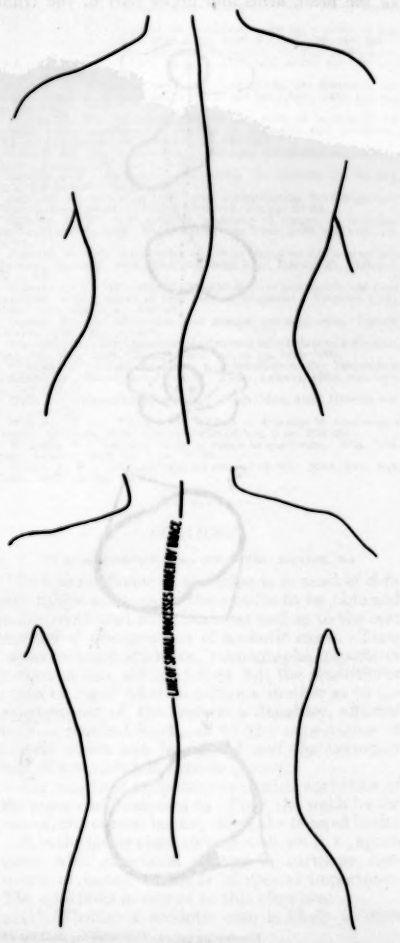

FIG. 3.

Tracings of case shown in Fig. 2 before and after application of brace.

of pressure which can be exerted by this apparatus is more than is ordinarily furnished by a removable plaster jacket.

The appliance is an ambulatory one and can be worn during the day time; in severe cases, however, it is important that there should be cor-

FIG. 2, *A*.
Case of scoliosis before application of brace.

Resistant lateral curvature in a girl of fourteen before treatment with plaster jackets.

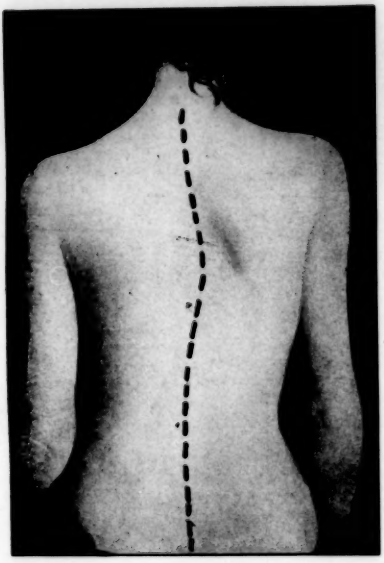

FIG. 4, *B*.

Same case after three month's treatment with two plaster jackets.

rection at night as well as day, and as the trunk changes its shape in the recumbent and standing position to a degree, a night brace can be made to exert a more effective lateral pressure, the patient being recumbent, than is possible with a day brace, while the patient is erect. For this purpose plaster or leather removable appliances with attachments furnishing increased pressure at desired parts made from a corrected plaster cast will serve; they should be made long, holding the pelvis and upper thighs, and should reach to the neck.

The most effective method of straightening a scoliotic curve is undoubtedly that exerting constant pressure by means of a permanently worn corrective plaster jacket. As it is non-removable, it exerts a constant correcting force.

There are many ways in use for the application of corrective plaster jackets. The method preferred by the writer has already been described and need be mentioned here briefly. It consists in placing the patient during the application of the jacket in as corrected a position as is practicable by means of straps pressing upon the convexity of the patient's trunk and connected with the four uprights of a gas-pipe frame, in the center of which the patient is seated.

The amount of correction at any one sitting is to be gauged by the patient's endurance, as well as by the stiffness of the curve.

It is manifest that a plaster jacket should be arranged so as not to press upon the concavities, and, if the curve is not a low one, that the jacket should reach above the shoulder and include the neck. By the judicious cutting of windows, room for expansion of the trunk concavities can be given without interfering with the corrective value of the corset.

It is inadvisable to continue the use of a non-removable stiff corset for longer than three months, but constant pressure correction should be continued in all resistant cases for a long time after the removal of a permanent jacket, usually during the period of active growth.

Removable plaster, leather or celluloid jackets are of service, but the brace mentioned by the writer has certain evident advantages and its efficiency demonstrated to the writer after through trial in the last three years.

The value of daily special exercise is incontestable. Exercises are to be used not only to strengthen the muscles, but also to restore flexibility to contracted portions of the spine. The subject of special exercises, however, is one which does not come in the scope of the present paper. Such exercises can be made so as to require little apparatus, and directions can be given to an intelligent mother or nurse, with change from time to time with the child's growth. The exercises should be taken daily and can be in part done at home. Although these exercises may be simple in execution, they need to be carefully planned for a definite purpose, changing with the changes in the patient's condition. For this reason they require careful direction from time to time from a surgeon of experience in treating of scoliosis in its different stages and development. The directions for changes in exercises in the use or removal of pressure appliances should be given at stated intervals, varying in frequency with the condition of the patient.

During the past thirty years a number of cases of scoliosis have presented themselves for treatment to the writer. In many of these careful record was made as to the progress and results of treatment. In some cases the condition several years after treatment had ended was noted. All known means of treatment were tried in these cases, and in many the value of new and suggested methods was tested. Out of several hundred cases, the following have been selected as illustrative of the different measures which will be found beneficial.

Light case with structural changes treated by exercises:

Case 1. F., young lady sixteen years of age, with curve as indicated in the accompanying measurement record, was treated by flexibility and development exercises for a few times a week, for a year, with exercises at home. The effect is indicated by the measurements. The patient was seen again when a woman of twenty-eight and her back carefully measured, showing that the improvement gained in the year of treatment had persisted. She was in excellent health and was without noticeable deformity.

Case with slight structural change:

Case 2. B., twenty years of age, with slight structural curve, treated for a year by corrective gymnastics and the application of a light brace for a short time. Seen two years after the cessation of treatment, while a college student. The gain in correction from treatment remained after the cessation of treatment.

Slight stiff curve treated by exercises:

Case 3. N., a lady of twenty-eight, with a slightly disfiguring curve causing projection of the right hip and a slight prominence of the shoulder, with the annoyance in the fitting of the dress and the necessity of wearing a pad. This patient desired every effort to be made to bring her figure to as near a normal standard as possible. As the curve showed structural changes no expectation of benefit from treatment was entertained, but flexibility exercises were tried as an experiment and carried on with assiduity by the patient, except with such interruptions as were occasioned by summer travel. At the end of two years marked improvement was indicated by the measurements which were taken. This was so evident that it was noted by a dressmaker, who furnished her with a dress after an interval of two years, a marked change in the measurements being needed for the hip and shoulder. No padding was required, though needed two years before this, and the patient, both on inspection and measurement, showed apparent perfect equality of the hip lines; the shoulders became even, and the figure, even to a critical observer, was admirable when seen in the ordinary costume without pads. The treatment was helped by some arrangement of the corsets which were worn part of the time each day. Correction would not have been possible without the pertinacity of the patient, who devoted herself to the correction of the figure with an assiduity comparable to that of a professional dancer, or an athlete anxious to preserve agility and form. The case is of interest as showing what can be done in exceptional instances. The benefit persisted several years after the cessation of active treatment, the patient keeping up daily light home gymnastics.

Rigid fixed curve in an adult, temporarily benefited by correction exercises:

CASE 4. Mrs. H., forty years of age, afflicted with a severe curve with marked rotation, causing great disfigurement, and limiting comfort and activity, with pain when superimposed weight was applied. The patient for a few months submitted herself to correction treatment, chiefly with the use of a recumbent correction with a lever pressure applied two or three times a week. Marked temporary benefit was obtained, as was shown by the relief from discomfort and pain in walking. The benefit was temporary and followed each treatment. This benefit persisted for a short time after the cessation of treatment, which was not carried on for more than a few weeks. The patient was seen two or three years later and her condition of disability had not been permanently relieved.

Correction by plaster Paris jackets:

CASE 5. W., a girl of fourteen with bad structural curve, treated for four months by corrective plaster jackets with the result indicated in the accompanying illustration. Four jackets were applied, the first with a certain amount of force. At the end of this time a leather jacket was worn for a short time and her treatment was discontinued. The patient was seen two years later and had relapsed to nearly though not into quite as bad a position as before treatment. The subsequent course of the case was not known.

Gymnastic treatment of scoliosis:

CASE 6. W., a strong girl of fourteen, was presented with a marked lumbar curve with some structural change. The patient was treated purely by gymnastics, which were carried on for several years with care. When older, heavy gymnastics, the use of 20- and 40-lb. dumb-bells, was carried on for several months The condition of the patient, when seen three or four years later, just before marriage, showed that the back was in excellent condition, with slight projection of one hip. There had been no increase of the lumbar curve. The patient's strength and carriage was excellent, without noticeable deformity except when the bare back was examined. This case illustrates the fact that structural curves may not increase and that the back may be strengthened and a practical benefit obtained by gymnastics.

CASE 7. P., a girl of twelve, rapidly growing, was treated in the same way as above, dumb-bell gymnastics being enforced and carried out for two years at home, under occasional direction, changing the exercises from time to time. The curve was a scoliotic curve with rotation, and the growth was rapid. The patient was seen four years afterwards and there had been an improvement in the figure, both in strength and contour. Her back was strong and in good condition, without noticeable deformity except when the bare back was examined.

Curve in a growing boy improved during growth, without treatment:

CASE 8. P., a boy of twelve, growing rapidly, presented an habitual curve without evidence of structural change. As treatment was not feasible, he was told to report occasionally for examination. At the end of two years his figure by the natural process of growth and the increased strength due to growth, or athletic activity, had changed in a way so that the curve had become less noticeable and was not sufficiently serious to demand treatment.

Cases treated by means of constant use of corrective braces:

CASE 9. B., a girl of fourteen, with marked curve, treated by means of the application and constant use of light apparatus such as is shown in the accompanying illustration. After a year's treatment improvement was noticeable, but the use of some form of pressure apparatus was continued.

CASE 10. R., a child of six, with bad scoliotic curve with structural changes. Treated by means of a pressure apparatus for six months, showing at the end of that time improvement in figure. The case is still wearing apparatus, which is changed as the figure improves.

CASE 11. P., badly deformed girl of eight; treated by the constant use of plaster and leather jackets for years. The deformity in this case followed some muscular distrophies of a nervous origin. Under the constant use of plaster and leather jackets for years, the patient's figure improved decidedly. Forced correction with plaster jackets was tried for a month, with the patient placed in bed, wearing a recumbent plaster correcting jacket, with improvement. The patient presents an illustration of improvement rather than cure of scoliosis.

CASE 12. G., a growing boy of sixteen, healthy and strong, with a bad curve, treated by means of corrective plaster jackets and leather jackets for a year, followed by the application of a brace, with marked benefit, which persisted six months after the cessation of treatment.

These cases are sufficient to indicate that a certain amount of benefit can be obtained in almost all cases of scoliosis by treatment; that in growing children benefit can be promised by assiduous treatment, even in the marked types of deformity, such benefit being permanent.

The essentials in treatment of scoliosis can be mentioned as follows:

First: A careful examination of the condition of the back, not only as to the curves and contour, also to the normal rigidity and lack of strength of the back muscles.

Second: Where needed, the use of such exercises as will strengthen the muscles, and such flexibility exercises as will correct abnormal stiffness. These flexibility exercises must be carefully applied so as to stretch at the part of the maximum stiffness, and not increase the flexibility of the flexible portions of the spine.

Third: In the more severe cases the constant use of some form of pressure appliance, with the pressure applied to the convexity of the curve, and without pressure on the concavities.

Fourth: These cases need oversight and direction at stated intervals during a long period. That is, during the rapidly growing years such oversight and direction should be given by some one familiar with the course of affections of this class. Such patients also need the constant direction of a parent or nurse or physician who will enforce strict and persistent attention to the details of treatment, and of a family physician who will pay attention to the observance of the laws of health, diet, metabolism, etc.

Fifth: The affection is not to be regarded as a disease, but as a fault in growth, and for this reason care is needed for the patient during the growing years.

The combined efforts of a family physician and expert specialist are of benefit in cases with this distortion and gratifying results may be expected to reward persistent efforts.

ON THE ABSORPTION OF PROTEIN AND FAT IN PULMONARY TUBERCULOSIS.

BY A. E. AUSTIN, MABEL ORDWAY AND RUTH MONTAGUE, BOSTON.

COMPARATIVELY few efforts have been made to study the metabolism of phthisical patients, possibly because of the fact that before the institution of sanatoria for the treatment of this class of patients it was difficult to control the food and excretions for analysis; since the establishlishment of these sanatoria, however, these difficulties have been overcome and, furthermore, we have had an opportunity to study the effects of what may be called supernutrition, since, in the efforts to overcome the emaciation associated with this disease, a dietary containing 5,000 calories is often offered the patient in twenty-four hours. Among the earlier efforts in this direction was one by Goodbody, Bardswell and Chapman in which, while the average daily food contained 3,500 calories, in some instances it was carried to 4,187 calories, and in one instance to 5,026. Fat was unusually well utilized; in one individual, with an ingestion of 231.32 gm. of fat during twenty-four hours, 96.41% was absorbed. It was found that when a largely increased amount of fat was given a healthy individual, used as a control, the feces showed a large increase in this ingredient, but this was not true of the tuberculous. Vannini and Collina have also investigated the metabolism of three sufferers from pulmonary tuberculosis and found that when the gastro-intestinal tract was unaffected, the absorption did not differ much from that of the normal individual; there was, however, in two cases, a greater loss of nitrogenous material in the feces than is customary, but they were only using a diet containing 70 gm. of albumin and a calory content of only 1,800. The fat in the feces varied from 8.91% to 14.45% of that contained in the food, a result much inferior to that found by the previous authors, who found a loss of only 3.59%; the difference depends on the amount given, and we may conclude that with an increase in the amount of fat ingested there is apparently a less percentage of loss.

NATURE AND PERIOD OF EXPERIMENT.

Owing to the courtesy of Dr. Dunham, three patients in the Massachusetts State Sanatorium at Rutland were placed at our disposal, and apart from some change in diet, all other features pertaining to the regimen there as to exercise, baths, etc., were observed by the patients under investigation. F. G., one of the patients in question, weighed at the beginning of the investigation 64.7 kgm. and had a temperature of 100.5°. At its close his weight was 68.07 kgm. and his temperature, 98.4°. The second, A. C., began with a weight of 67.5 kgm. and a temperature of 98.6°, and concluded with the weight of 67.6 kgm. and a temperature of 98.6°. A record of McI.'s weight and temperature was apparently not kept. All three were placed on the ordinary house diet for a period of eleven days in order to accustom the individuals to the increased food, but the portion of every article was weighed which was eaten by each individual in its cooked condition, and from the tables of Atwater its protein, fat, carbohydrate and calory value determined. The average of these eleven days was a daily amount of protein, 172.39 gm.; of fat, 176.45 gm.; of carbohydrate, 420.85 gm. and 3,774.12 calories. Then followed a period of five days when the protein was increased and all portions carefully weighed and their constituents calculated as before; during this period, the urine and feces were collected and the nitrogen of the former and the nitrogen and fat of the latter quantitatively determined; the nitrogen was determined by Kjeldahl and the fat by extraction of the dried feces with ether in a Soxhlet apparatus and the residue weighed; double estimations were always made and the average of only two fairly closely corresponding results taken. Unfortunately in the transportation of the urine from Rutland to the chemical laboratory of Tufts Medical School, more or less decomposition of the urine took place and nitrogen was lost as ammonia, so that in this respect alone the results were valueless and are omitted. The diet was now changed, and, by means of olive oil, the amount of fat given was increased without lowering the amount of nitrogen, and, after two days on this diet, a collection of urine and feces was made which were analyzed quantitatively as before for five days. During this period, in order to increase the amount of fat, olive oil was given daily in amounts from 45 to 60 gm. The patients were kept upon this diet until Feb. 25, when another period of five days was inserted during which, by the use of olive oil, cod-liver oil emulsion and butter, the fat ingested was largely increased and again the feces examined quantitatively for fat and nitrogen. During the second period, hyocholalic acid which is prepared and sold by Rufus Crowell Co. under the name of Colalin, and included in the list of new remedies by the Council of Pharmacy of the American Medical Association, was given in doses of 1½ gr. daily. Thus we have the opportunity of comparing the absorption of fat in this period of moderately increased fat consumption with slightly increased fat in the first period and excessively increased fat in the third period. v. Fuerth and Schuetz have shown that the favorable effect that the bile salts have upon the splitting of fats is due to the cholalic acid. It has also been found that 50% to 80% of the cholalic acid which enters the intestine from the bile duct is reabsorbed. Whether the hyocholalic acid, which is unlike in many respects the bovine cholalic acid, follows this law, it is difficult to say; at least in two individuals with biliary fistulæ established for the cure of cholelithiasis, no cholalic acid could be precipitated from the bile which was secreted, nor after the ingestion of hyocholalic was there any more evidence of the presence of a cholalic acid; of course it would not be safe to say that it was not present, but it must have been very largely diminished, and certainly the evidence was against the absorption of the foreign bile acid whatever may happen to the native acid. In order to present the protein, fat, carbohydrate

and calory value of the food of these three patients during the three periods mentioned of five days each, the following table is appended:

C. (L. M. Annex.)

Average per day.	Proteins.	Fats.	Carbohydrates.	Calories.
Period 1. Feb. 2 through Feb. 6.	207.63	162.02	558.743	4632.9153
Period 2. Feb. 8 through Feb. 12.	199.16	192.83	533.58	4797.553
Period 3. Feb. 25 through March 1.	197.77	354.88	541.83	6332.744
G. (Ward E.)				
Period 1. Feb. 2 through Feb. 6.	206.76	160.57	477.58	4299.095
Period 2. Feb. 8 through Feb. 12.	223.00	214.65	413.6	4577.305
Period 3. Feb. 25 through March 1.	186.97	425.88	461.66	6619.067
McI. (Ward E.)				
Period 1. Feb. 2 through Feb. 6.	185.72	158.71	427.3	3989.385
Period 2. Feb. 8 through Feb. 12.	181.02	212.375	312.23	3997.412
Period 3. Feb. 25 through March 1.	159.52	371.2	276.2	5238.59

The amount of albumin to be given to a healthy individual is stated as from 1 to 5 gm. per day, and kilo and the calories as 35, based upon the same factors, so that upon this standard, calculated upon C.'s weight, the upper limit of protein feeding would be 307.5 gm., a limit reached by none of the patients during this series of experiments. The patients were allowed to satisfy their appetites as far as quantity of food went, being restricted only in the character of the food, but each article was carefully weighed, so that the amounts vary; for instance, A. C. consumed more food than his companions, but the increase consisted in the greater amount of carbohydrate of which he partook. Furthermore, while the amount of protein remains practically the same in all three periods in A. C.'s dietary, the other two compensated for the increase in fat by diminishing their protein, and McI. by taking less carbohydrate as well. In the extraction of fat from the feces no effort was made to separate the fatty acids from the neutral fats, but the mass was always made acid before the extraction, so that the fatty acids in the shape of soaps should be included. The lecithin, too, of the food, a portion of which escapes absorption, is also included, but this portion must always be small since the major part of the phosphorus which it contains is always found in the urine, showing its disintegration and absorption.

The eliminated nitrogen, too, in the feces comes from two sources, — the residue of the digestive secretions and the desquamated intestinal epithelium as well as from the unabsorbed protein of the food, but it is practically impossible to separate one from the other, so that it is usually reckoned in the nitrogen from waste food products. No attempt was made to determine the weight of the moist feces, but the entire five days' quantity was placed in a weighed evaporating dish and, with the aid of alcohol, was dried to a constant weight and then aliquot parts were taken for the separate estimations. This method has been recently criticised because there is danger of losing a portion of the volatile nitrogenous products, chiefly ammonia; this was avoided as much as possible by the addition of acid when strictly alkaline; the weighing and separation of moist feces is associated with so many difficulties, and from the unequal distribution of the water is so inaccurate, that the former method, in spite of the loss, is the more accurate. A table of the average daily elimination of fat and nitrogen in the feces for the five days is appended. As is well known, the percentage of loss of fat and protein or, rather, nitrogen, varies very largely with the character of food, its preparation and amount; taking first, for instance, the nitrogen loss in the feces, though the nitrogen comes both from the food remnants and from the intestinal secretions as well as from the desquamated epithelium, it is very difficult to separate these two factors, so that it is permissible to compare the intake with that which is eliminated. Compared in this way, it is found that the percentage of

C. (L. M. Annex.)

Average per day.	Feces.	Nitrogen.	Fat.
Period 1. Feb. 2 through Feb. 6.	19.836	.3925	1.8308
Period 2. Feb. 8 through Feb. 12.	9.810	.3606	2.0002
Period 2. Feb. 25 through March 1.	8.209	.3960	1.6647
G. (Ward E.)			
Period 1. Feb. 2 through Feb. 6.	34.36	.4933	5.0820
Period 2. Feb. 8 through Feb. 12.	18.50	.5469	3.9003
Period 3. Feb. 25 through March 1.	41.298	1.2612	5.565
McI. (Ward E.)			
Period 1. Feb. 2 through Feb. 6.	37.960	.6473	4.9217
Period 2. Feb. 8 through Feb. 12.	30.715	1.0316	6.4562
Period 3. Feb. 25 through March 1.	25.812	.9108	4.8149

loss is much greater when the nitrogen intake is small than when it is large; furthermore, with a diet containing a large amount of nucleo-proteids like liver and sweetbreads, the comparative nitrogen loss is much greater, and finally on the same diet Von Noorden found variations of from 4% to 10%, and the loss also might vary from time to time in the same individual. Magnus-Levy found that on a mixed diet, containing 100 gm. of protein, the loss in the feces was from 1 to 2 gm., making a loss of 6% to 10%. In the cases reported here, however, it is impossible to compare the loss with that of average protein ration for the reason stated above, and we must look for examples of increased protein feeding; such an example can be found in the experiments of Luethje and Berger on an individual convalescing from typhoid fever who ingested protein daily containing 54.6 gm. of nitrogen with a loss in the feces of 3.4 gm., or a procentual loss of 6.2%; of free fatty acids tend also to increase the absorption of fat, but the suggestion of Von Mering that free oleic acid be added to fats is not absolutely necessary, since as far as is known the healthy intestine is able to hydrolize fat in unlimited quantities, nor is this power apparently lost in those chronic cases where cod liver oil is used. Even where the steapsin is diminished or lacking through disease of the pancreas, the intestinal bacteria seem able to split a large proportion of the ingested fat. It is only in forced fat feeding that the inability to split the fat would seem to be suspected, and here, where fat to the extent of 425 gm. daily in the case of G. was ingested, there appeared no great increase in the percentage of loss.

A table is here appended showing the percentage of loss in the feces of both nitrogen and fat, arranged according to the succession of periods in each patient. From this we are at first attracted by the astonishingly small percentage of loss in

Period.	Nitrogen intake.	Nitrogen in feces.	Per cent nitrogen lost in feces.	Fat intake.	Fat in feces.	Per cent fat lost in feces.

the increase of weight of the individual during a period of seven days was 900 gm., while C. in a five days' period with 33.22 gm. of nitrogen in the daily intake of protein, and a loss of 0.392 gm., put on 659 gm. weight; the daily amount taken on by C. was 131 gm., and by the convalescent from typhoid, 127 gm. With the fat, too, there is no disappearance during fasting; during a prolonged fast Cetti eliminated 1.3 gm. of fat per day and Breithaupt, 0.57 gm. Rubner as well as Klemperer has found that if the fat be in assimilable form, like butter, olive oil or cod liver oil, a human can take 200 gm. of fat with a loss of only 2 to 3%; Landergren also found that as much as 340 gm. of fat could be taken by a human, if mixed with a little alcohol and mucilage, with a loss of only 4%. The percentage of loss of fat also follows the same law as that of protein; that is, as the amount of fat taken increases, the procentual loss becomes less and less up to a certain point which has apparently been never fully determined. It has been established that if the day's ration contain but 25 to 40 gm. of fat, the loss may be from 10 to 15%; if, however, the amount be increased to 80 to 100 gm., the loss will be only 2 to 4%. The melting point of the fat also affects its absorbtion; the fluid oils are much more absorbable than the solid fats and, what is more important, the addition of a fluid fat to a solid increases the absorption of the latter. The amount

general both of nitrogen and fat, showing that the absorptive power of the pulmonary tuberculous not only equals that of the healthy adult, but even exceeds it. Still, an individual peculiarity can be seen particularly in the utilization of protein; C. has the best absorptive power, though taking much more protein than McI., his loss is only about one half as much. Of course we cannot say absolutely that the former has the better absorptive power until we place them both upon the same amount of protein, as we have already learned that the percentage of loss diminishes with the increased amount of daily consumption. Any changes which may occur in the absorption of the tuberculous is due to the disease *per se* and not to the accompanying temperature, for Von Noorden's patient, suffering from tuberculosis, but with no temperature, when taking 11.6 gm. of nitrogen daily in the form of albuminous food, showed a loss of 8%, and of the 85 gm. of fat taken daily, a loss of 7%. Six days later, with the same diet, but with a high temperature produced by the effect of tuberculin, the loss of nitrogen in the feces was 8.4% and of fat, 7.3%; this variation is so slight that it may be neglected. This principle is universally true, so that, as v. Hoesslin remarks, the presence of temperature in tuberculosis, if pulmonary, need not deter us from trusting the intestinal canal to elaborate and absorb these enormous quantities of food necessary to

maintain the body weight. When we take the absorption of fat into consideration, we find a slight diminution in the loss in the case of C. as well as in that of McI., while in G. the diminution is very marked; how much of this is due to the use of hyocholalic acid is difficult to say, since there is found a much more marked diminution of loss between the second and third period. Two other factors come into play here; in the first place an increased ingestion of fat, as above stated, always diminishes the procentual loss, and the increase here is very marked, being respectively 62, 211 and 159 gm. Furthermore, this increase was made up largely of olive oil, an easily digestible fat, on account of its low melting point, and this undoubtedly rendered the other fats with higher melting points, like beef and mutton tallow, to be more readily absorbed and hence in larger quantities. For instance, of stearin alone, with a melting point of 60°, there is lost in the feces 86 to 91%, but when it is given with almond oil with a melting point of 55°, there is a loss of only 10.6%. Cod liver oil, which has no inherent value in phthisis, but which must have had some basis for its long popularity, probably acts in the same way on account of its low melting point. This admirable absorption of nutriment under the regimen of the sanitarium treatment of the tuberculous, although such enormous amounts of food are given, is probably due to two reasons: First, the ration is well balanced, and it is well known that under this condition the absorption of any one form, protein, for instance, is much better when given with a corresponding quantity of fat and carbohydrate than when given alone in large quantities; secondly, the human body, provided that the intestinal tract is normal, absorbs nourishment according to its needs, much as a sponge takes up water according to the state of dryness existing within it. In only one instance was there any appreciable increase in weight, a condition only to be explained by the fact that, in spite of the great absorption, barely enough tissue building material was obtained to replace that which was destroyed by the action of the disease upon the tissues.

A RAPID PRESUMPTIVE TEST FOR DIARRHEA CAUSED BY THE GAS BACILLUS.

BY ARTHUR I. KENDALL, PH.D., AND RICHARD M. SMITH, M.D., BOSTON.
(From the Boston Floating Hospital and the Department of Preventive Medicine and Hygiene, Harvard Medical School.)

DIARRHEA in infants may arise from a variety of causes. Micro-organisms play a part in the production of diarrhea in many cases. The action of the dysentery bacillus in this connection is well known. It has been definitely shown by other observers that the gas bacillus also, or B. Welchii as it is more properly named, may be the causative factor in some cases of diarrhea. There has been no simple method applied, however, to the detection of this organism in the stools of suspected cases, and it has, therefore, been difficult and almost impossible for clinicians to arrive at a definite diagnosis. This difficulty of diagnosis is further complicated by the fact that certain cases in which the past history is uncertain, present, at the time of examination, stools characteristic of bacillary dysentery, i. e., they contain blood, pus and mucus.

In order to throw light upon the distribution of the gas bacillus in the stools of children with diarrheal diseases, we have utilized the abundant material upon the Boston Floating Hospital. The method employed in detecting the gas bacillus is simple, rapid and certain.

The method consists essentially in inoculating sterile tubes of whole milk with a small portion of the suspected stool, thoroughly emulsified in it, and immersed in a water bath to above the level of the top of the milk and heated to 80° C. for twenty minutes, incubating at body temperature for eighteen to twenty-four hours. As an alternative procedure, the infected milk tube may be gradually brought to the boiling point of water in a water bath, kept there for three minutes, then incubated as above. By so doing, all bacteria not in the spore state are killed, and the development of the spores into vegetative cells is unrestricted by the presence of non-spore-forming organisms. Those cultures containing gas bacilli present at the end of the period of incubation three prominent features: (*a*) The casein is largely dissolved (usually at least 80%); (*b*) the residual casein is slightly pink in color, and filled with holes, the result of the stormy fermentation; (*c*) the culture smells strongly of rancid butter, due to the formation by the gas bacillus of butyric acid. Gram-stained preparations made from such growths show rather thick, short bacilli with slightly rounded ends. Controls suitably studied culturally have shown that cultures presenting this complex are in reality gas bacilli.

Very frequently "pseudo-reactions" occur; there is, as above, a decided liquefaction of the casein, but the shotted appearance of the residual casein is absent, and there is no odor of butyric acid. These growths have been found to contain *B. subtilis*, or members of the subtilis group, and are not to be regarded as even suggestive of B. Welchii.

We have examined by this method the stools from 231 infants presenting a variety of intestinal disturbances and a few other diseased conditions. It was possible to isolate the gas bacillus from 22 cases. Six of these cases had apparently normal stools; 2 had thin watery stools with a few curds and a little mucus; the remaining 14 showed blood and mucus and many of them pus in the stools. The clinical diagnosis of these 14 cases was uncertain, but suggested bacillary dysentery.

It was not possible in any case in which the gas bacillus was recovered from the stools to isolate simultaneously the dysentery bacillus. It would appear from these cases, and from bacteriological studies upon dysentery cases, to be reported later, that the conditions favoring the development of the gas bacillus in the intestinal tract are unsuitable for the growth of the dysentery bacillus.

The gas bacillus is present in small numbers in the stools of some older bottle-fed babies which are apparently in perfect health, and this might at first sight be construed as an argument against the specificity of the organism in cases of diarrhea. It will be found, however, that this inconsistency is more apparent than real, for it is well known that other pathogenic organisms, e. g., the pneumococcus, may exist as apparently harmless saprophytes in the body. Those cases in which we regard the presence of the gas bacillus as significant and as the etiological factor of the disease give a history of diarrhea of greater or lesser severity, and usually of rather long standing, so that the intestinal tract has had ample opportunity to rid itself of the majority of its bacterial flora. The fact that the gas bacillus finds a suitable environment for its rapid proliferation in a certain number of these cases lends additional evidence to the etiological relationship of the organism.

The diagnosis of diarrhea due to an infection with the gas bacillus can be made by the means described above within twenty-four hours, at the end of which time it is possible to begin treatment with a definite idea as to the etiology of the condition. The management of all acute diarrheas during this period of twenty-four hours while the cultures are developing and while the diagnosis is being made is practically the same, namely, purging and starvation.

Thus far the application of the method as outlined above and the subsequent treatment with buttermilk has been limited to relatively few cases, but the results obtained have been uniformly satisfactory and would seem to justify the belief that the gas bacillus is the etiological factor in a small group of the acute diarrheas in infants.

Clinical Department.

TWO CASES OF COMMON SPEECH AND VOICE DEFECT AND THEIR TREATMENT.

BY ABRAHAM MYERSON, M.D., BOSTON.

Medical literature so often concerns itself with rare conditions and difficult therapeutic problems that one feels like apologizing for reporting cases that are common and whose treatment is along well-known principles. The only excuse the writer has for taking up space with the two following cases is that they represent conditions that on the whole are neglected by the medical profession of America. Speech and voice defects have an importance to the patients suffering from them that gives dignity to their consideration, and they are so frequently associated with nervous disorder as to make a proper working field for neurologists. A profession that claims the whole range of human pathology as its field cannot consistently neglect conditions of this kind. Our duties as physicians so often end with naming the ill we cannot cure that we ought pay particular attention to those diseases in which patient effort is rewarded with brilliant success.

The first case is that of a young woman of twenty-eight, referred to the writer by Dr. E. A. Crockett. The patient has a good family history, was born at full term and in a normal manner. Aside from the matter of speech, her development, including the time of teeth eruption, walking, dextrous use of hands, learning of cleanly habits, was normal. She learned to speak at the usual time, but, as related by her mother, never talked plainly, a defect which became more marked as she grew older. However, she did not seem mentally deficient, for she went through grammar school without trouble and was in every way decent and well behaved.

Examination showed that ears, nose and throat are normal. Intelligence is up to the average of servant girls, that being her occupation, and she can spell and write very well, in fact, better than the average. In other words, she is neither deaf nor feeble-minded, the usual causes of defective speech, and one can only account for her unintelligible speech by stating that some acute illness which came and went unnoticed left a defect which was neglected, grew worse with the years, and mal-directed her whole life.

Unintelligible is a short description of her speech. Its three main defects arose from her consciousness of inferiority, and represent compromises between her need of speech and her wish to avoid it. First of all she spoke in what was almost a whisper, so that, for example, there was little difference between such sonants as *b*, *d*, and the correspondng surds, *p*, *t*. Secondly, she used only the tip of her tongue, her teeth and lips, in speech, so that sounds like *l*, *r*, *k*, *g*, *ch*, etc., were entirely missing, and *t*, *p* and *b* obtruded themselves continually. Third, she opened her mouth as little as possible, and so there was a disagreeable nasal tone to her voice.

The treatment was and still is re-education. She has been under the writer's care for four months, appearing on an average of once a week, which, of course, is utterly inadequate for quick results. Nevertheless, her progress has been satisfactory, for while some sounds, notably *ch* and consonant *j*, are still very difficult, she can use all the others sufficiently well to frame an ordinary conversation. There is no doubt that in time she will not be markedly different from her neighbors so far as speech is concerned.

The details of her speech training are not interesting, representing as they do the utilization of well-known principles. Perhaps it is of value to state that the writer has found it much easier and more expedient to place instrumentally tongue, lips, teeth, etc., in the places proper to any sound than to show where to place them by diagram or by looking-glass. In other words, the motor memories are more valuable than the visual as the basis for learning the reproduction of speech sounds, while the fact that such defects as these arise in a community of normally speaking people proves that auditory memories, the usual basis of speech, are by no means the best to utilize in re-education.

What is here necessary to emphasize is this: that the chances of "outgrowing" speech defects, the usual consolation offered to parents of such children, are few as against the chances that the trouble will get markedly worse. And where so socially important a function is concerned, where defect

means occupying an isolated and inferior position throughout life, with its accompanying distress, there is a moral issue involved in such advice as well as one purely medical.

The subject of re-education, as well as phonetics in general, is well covered in the writings of A. Graham Bell,[1] E. W. Scripture,[2] H. Gutzmann,[3] and particularly in the French [4] and German [5] periodicals which concern themselves almost entirely with speech.

The second case, one of partial aphonia, concerns a lady of fifty, a well bred, cultured woman of wealth and high social standing. Her occupation, the dispensing and directing of charity, compelled her to speak a good deal, but is only in part responsible for her trouble. About ten years ago she commenced to suffer from "sore throats" and hoarseness, which at first appearing only in the winter, finally came in the summer as well. Routine laryngological measures directed to nose, pharynx and larynx were of no avail, and finally her voice became very weak and practically devoid of laryngeal tone, — in other words, aphonic.

The examination disclosed no abnormalities beyond the following:

1. A very slight imperfection in the adduction of the chords, the larynx being otherwise normal.

2. On phonation, the shoulders were raised and the upper chest and neck muscles became rigid, meaning that expiration became spastic.

3. Writer's cramp of the right hand, of a flaccid type, and so marked that the typewriter was her usual means of correspondence.

The treatment was directed toward establishing correct habit of managing the column of air necessary for phonation. On the theory that the defect involved the whole of the respiratory act during speaking, she was directed to make her breathing of the type known as lower costal and to lengthen the expiration while practicing graduated vocal exercises. With the looking-glass as her guide, she learned to speak without drawing up her shoulders and with the upper chest relaxed. The result of a month's persistent training was that she was enabled to pass the following winter without a cold, and she could speak freely and with ease, although her voice remained low, but not aphonic.

The literature regarding such cases dates back for many years, and there are some writers whose opinions are of interest and value. That the laryngeal condition is an effect and not a cause was emphasized by Piorry [6] as far back as 1822, but even to-day laryngological treatment is mainly directed to the local condition, without regard for the fact that "function can undermine itself and its organ," as Meyer [7] puts it. Since Piorry's time many eminent laryngologists have considered the condition carefully both as regards its etiology and treatment. Thus Holbrook Curtis [8] regards it as resulting from the wrong management of the column of air, of a vicious and "upper chest" type of respiration. Lenox Browne,[9] and his co-worker in voice culture, Behnke, agree with this, but differ in regard to the therapeutics. They hold that diaphragmatic breathing is the only proper kind for all vocal effort, while Curtis believes that lower chest respiration is better, as being more amenable to the will, and states that most great singers breathe in this way while singing. Gutzmann,[10] who regards the trouble as spastic, and whom the writer [11] has quoted elsewhere, agrees with Curtis, quoting Sewall and Pollard [12] as having conducted experiments to prove this. As a matter of fact, these laboratory workers prove as much for one side as for the other, since they show that diaphragmatic treatment is more favorable to air mixture and high tone production than is costal respiration, while this latter brings more air into the lungs and is better for low tones. Olivier,[13] in a fine comprehensive article, lays the trouble to insufficient inspiration and, therefore, directs his attention towards increasing the breathing capacity of his patients.

The noted laryngologist B. Fraenkel [14] declared that these patients were suffering from a laryngeal condition allied to writer's cramp for which he proposed the names "mogiphonia" or "phonasthenia." He stated that there were spastic, paretic and tremulous types of writer's cramp and similar types of this laryngeal trouble. As in the hand affection, he regarded as the etiological factors the excessive use of the part in a neuropathic individual; in other words, bringing it into what is nowadays classed as the "occupation neuroses." [15] On the whole he considered that the prognosis of these cases was unfavorable.

As a matter of fact, excessive use of the voice will bring about aphonia in any individual. Such cases are simple; they are not neuroses, but are states of chronic fatigue of a part. But in the case here reported, and in many others, there is no such history, for her troubles came on without real excessive speaking or singing. Nor do people as a whole have to learn to speak correctly, for while almost every untrained person has defective control and tone, he uses his respiratory apparatus in a manner which training only perfects. But the person who is intense in all that he or she does, who is exceedingly earnest, brings about an excessive innervation of the part he is to use. This excess brings about muscle spasticity; this spasticity brings on quick fatigue, which in its turn, when long continued, brings about loss of function. Thus ordinary people, not "neuropathic," when engaged in heated argument, speak in high-pitched voices, and examination will show that the upper chest is engaged in squeezing out the sounds, while the shoulders are raised and the abdomen is hard and tense. And the type above referred to not only constantly speaks tensely, but shakes your hand excessively, "goes into everything," as we say, with great zeal, and a use of musculature that is almost always spastic.

So at least a certain proportion of functional aphonia, greater than most laryngologists recognize, is due to misuse of the entire speech apparatus and not to changes in the larynx. It is necessary to emphasize the fact that the entire apparatus is misused in these abnormal speech efforts, just as it is normally used in its entirety in normal speech effort. Diaphragm, chest and larynx are all involved in the spasticity, — but the larynx suffers most. Moreover, infla nmatory and other organic changes in throat and larynx which are associated with pain and hoarseness are often not the causes of the changed functioning of the parts involved, but with the pain and

hoarseness are symptoms of the wrong use of the parts. Medical science is adding to the cellular interpretation of disease, the physiological or dynamic interpretation, and therapeutics can most profitably apply the lessons of pathology. The method of using any part that is normally operated by the will can be changed if it be a a wrong method to a correct one, at least in most cases. With that change will come a readjustment more or less complete of the parts to the normal. This is as true in laryngology as in orthopedics, and its recognition has an important bearing on the therapeutics of the future.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., AND HARVEY P. TOWLE, M.D.

1. Ecthyma Térébrant de l'Enfance.
2. Purpura Hemorrhagica Due to Benzol Poisoning.
3. Grain Itch.

ECTHYMA TÉRÉBRANT DE L'ENFANCE.

Welander[1] describes in an interesting fashion the case of a child of three who was admitted to the hospital suffering from peculiar ulcerations of the scalp, right hand and the buttocks. The history was that the first appearance was that of a pustule near the right thumb nail, from which an ulcer quickly developed. Two weeks later ulcers appeared, also near the anus and on the buttocks, as well as on the scalp. They extended, especially those upon the scalp, while new ones appeared in the vicinity. The ulcers were covered more or less with yellowish-brown crusts. Two months after the first appearances the child was admitted to the hospital.

When admitted the scalp presented a number of large and small ulcers partially covered with a crust. Some of these ulcers showed by their contours that they had arisen from the confluence of several smaller ulcers. Most of these ulcers were sharply defined, as if punched out. Small flat vesicles were to be seen in the vicinity of these ulcers. Similar ulcers were seen upon the right thumb, which had coalesced to practically one ulcerated surface, which extended to the back of the hand. On the buttocks and the lower part of the back similar ulcers were seen, not so sharply defined as those upon the head. The child's condition was very bad, with a rise of temperature.

[1] Welander, Stockholm: Arch. für Dermat. und Syph., xcix Band, 3. heft.

Soon after the child's entrance, staphylococci were found in the vesicles of the head with partially pustular contents. The Von Pirquet reaction was positive, the Wassermann reaction negative. No reaction from the injection of tuberculin.

In the further course of the affection it was shown that the first appearances were semi-transparent vesicles which extended peripherally, became necrotic and changed into flat ulcers with sharp edges, which quickly extended both in depth and peripherally.

Under applications of cyanide of mercury the ulcers gradually healed and the child made a good recovery.

The writer confesses that it would have been very difficult to make the diagnosis from the ulcers on the head alone had there not been present those of the buttocks which corresponded completely with the pictures of *ecthyma térébrant de l'enfance*. The evolution of the ulcers enables one to exclude tuberculosis as their cause. That the child also had tuberculosis was proved by the positive results of the Von Pirquet test, and later enlarged glands and a tubercular affection of the joint developed. The child's tuberculosis was said to have only an indirect action on these ulcers by lowering the child's power of resistance toward the action of the pathogenic bacteria which were the cause of the affection. This affection has been usually found upon the buttocks, although others than Welander have described its occurrence on other places.

It is clear that this affection is caused by some form of micro-organism. In some cases streptococci have been found; in others, the bacillus pyocyaneus. In Welander's case no positive result was obtained from the bacteriological investigations. Staphylococci were found in the vesicles. Streptococci were never found in an early stage. Once small short rods were found in the cultures made from the vesicles. On the whole the writer is inclined to believe that the staphylococci were the cause of the affection in his case. Certainly neither streptococci nor the bacillus pyocyaneus could be regarded as causative.

Whatever may have been the form of micro-organism that caused the affection, it can be confidently maintained that it began as a local lesion with infection from without, and that the pathogenic micro-organisms were carried from one place to another, causing the new infections. Absorption from the toxic agents caused the constitutional disturbance and the rise of temperature.

In conclusion, the writer asserts that the cyanide of mercury is much preferable in such skin affections to corrosive sublimate, in that its action is effective without having the strongly irritating properties of sublimate.

PURPURA HEMORRHAGICA DUE TO BENZOL POISONING.

In a preliminary report Selling[2] relates a number of cases of purpura hemorrhagica which occurred

[2] L. Selling: Johns Hopkins Hosp. Bull., Febuary, 1910.

at a factory in the suburbs of Baltimore engaged in the manufacture of tin cans. From the mode of occurrence, and from the results of experimental work, it is probable that they belong to the group of toxic purpuras.

The factory employed about three hundred and twenty-five people, and was divided into several departments. The cases were all confined to one department, and, indeed, to one room in this department, the so-called "coating room." In this room a substitute for solder was used which was a mixture composed of rubber, a rosin and a coloring matter dissolved in commercial benzol. The cases occurred among fourteen girls between the ages of fourteen and sixteen, who worked at the coating machines. After the can covers had been coated about the margin with the mixture which has been described, they were piled in trays and allowed to dry by the evaporation of the benzol. Ten gallons of benzol a day were evaporated in this room. There was a well-marked odor of benzol in spite of good ventilation and open windows throughout the room.

Three cases are then described, two of which were fatal. The symptoms were quite similar in all cases. The first appearances were those of a purpuric eruption, followed soon after by hemorrhages from the nose and mouth. In one case there was a very severe hemorrhage from the throat, which was with difficulty controlled by local applications. The patients who died gradually lapsed into a toxic condition for some time before death.

In the case of the patient who recovered there were marked gastric symptoms and the purpuric eruption was much less extensive than in the other cases. The condition of the blood in these cases has been described as the picture of aplastic anemia. There were only slight changes in the appearance of the red blood cells; there was an absence of regenerative forms, quantities of platelets and a diminution of the granular types of white blood cells, with a relative increase in the mononuclear elements.

A series of cases quite similar to these was reported from Stockholm in 1897, which occurred at a factory engaged in making bicycle tires and where benzol was used as a solvent for the rubber. Experiments made by Santesson, who described this epidemic, demonstrated that hemorrhages into the internal organs could be produced by wrapping the bodies of rabbits in cloths soaked with benzol and chemically pure benzene, as well as by subcutaneous injection.

Some other experiments were made by Selling by injecting fractional distillations of the mixture into rabbits, with the result that a great diminution in the white blood cells with the outpouring of a large number of abnormal forms occurred.

GRAIN ITCH.

Schamberg[3] publishes an interesting article on this subject based on a number of cases observed in Philadelphia. He first observed the affection in epidemic form in the spring of 1901, and it was then described under the title, "An Epidemic of a Peculiar and Unfamiliar Disease of the Skin." The cause of this disease was at that time obscure.

In the spring and summer of 1909 this same affection became very prevalent in and about Philadelphia. The discovery of its cause was due to an outbreak that occurred among twenty sailors on a private yacht in the Delaware River. Dr. Goldberger was detailed by the United States Public Health and Marine-Hospital Service to investigate the matter, and Dr. Schamberg and he continued the investigation together.

After examining the twenty sailors who had been sent to the hospital, they then turned their attention to the yacht and found that a number of new straw mattresses had been received and that the disease was confined to those who had slept on these mattresses or who had put their clothes on them. Eleven people on board the ship who had not slept on the new straw mattresses had not acquired the disease.

At the same time it was found that there was a similar affection among the sailors of four other boats in the vicinity, and it was found on examination that these boats had also obtained new straw mattresses. Many other cases were also investigated in different parts of Philadelphia, in which the affection could be traced in the same way to a new mattress.

It was found that all of the manufacturers who had furnished these straw mattresses had obtained their wheat straw from a dealer in southern New Jersey.

Schamberg and Goldberger then made a careful examination of the straw and were able to detect the presence of a mite of very minute size. This was declared by Mr. Banks, of the Bureau of Entomology, to be very close to, if not identical with, the pediculoides ventricosus.

It was proved that this was the cause of the affection by the production of characteristic lesions upon people who voluntarily slept on the mattresses for experimental purposes. Portions of the straw were also applied to the skin of volunteers and resulted in producing the same lesions.

The characteristic appearance is that of wheals which have a central small vesicle. The vesicle soon becomes a pustule. There are also two other types described as the varicelloid, with a large central vesicle or pustule, and the erythema multiforme type.

The eruption is usually profuse, involving the neck, chest, abdomen and back, and to a less extent the arms and legs. The trunk is the part most affected. The hands and feet are usually free.

The eruption is usually accompanied by intense itching, which is worse at night and leads naturally to violent scratching and resulting excoriations.

At first there may be some slight constitutional symptoms and at times a moderate enlargement of the lymphatic glands.

Examination of the blood showed:

(1) That there was in most cases a moderate leucocytosis during the acme of the disease.

[3] Schamberg: Jour. Cutan. Dis., Febuary, 1910.

(2) That the eosinophilia was well marked at the height of the affection.

(3) Both the leucocytosis and eosinophilia subsided with improvement of the symptoms.

(4) That the other leucocytic elements showed no particular changes.

The histological changes are essentially those of an urticarial lesion.

It is comparatively easy to get rid of the parasite. Schamberg uses an ointment of betanaphthol and sulphur. The clothing should be disinfected by boiling or fumigation. In the case of the mattresses they may be freed of the mites by exposure in a closed chamber to steam and sulphur fumes or formaldehyde.

Ordinarily the itching will cease within twelve to thirty-six hours, and the eruption disappear in a week or ten days. From his observation Schamberg believes that the affection dies out of itself after a time.

The writer found upon looking into the matter that an affection probably of the same nature has prevailed from time to time in different sections of the United States. A series of cases published in England last year under the title "Barley Itch" may possibly belong in this category; also a study of the literature reveals many instances of cutaneous affections occurring in people who had come in contact with some sort of grain that were very probably due to this mite. As far back as 1829 "Fessenden's New England Farmer" published a communication regarding a disease of barley straw which was produced by the puncture of insects.

The pediculoides ventricosus is parasitic upon the larvæ of soft-bodied insects, and it is of importance from the fact that it is hostile to the grain insects, and, therefore, favorable to the preservation of the grain. It was also found that straw used for packing purposes and sacks of wheat and barley and other grains constitute additional sources of infection.

AMERICAN SURGICAL ASSOCIATION.

Meeting at Washington, D. C., May 3, 4, 5, 1910.

OPERATIVE TREATMENT OF TUMORS OF THE HYPOPHYSIS.

A. E. Halstead, M.D., of Chicago: A survey of the literature on the operative treatment of tumors of the hypophysis discloses the fact that many of the procedures proposed are based not on clinical experience, but on observations made in the post-mortem room; therefore, the merits of these methods are still unproved. The routes of approach previously advocated have been the intracranial and the extracranial. Halstead proposes what he terms the oro-nasal route, which he employed successfully in one case. It is a modification of the infranasal method of approach, but is without the trauma and disfiguration which must follow the Koenig operation.

Halstead presented a patient showing the extremely good result obtained by this method of procedure. He also reported a fatal case.

DISCUSSION.

Dr. S. J. Mixter, of Boston: I wish to present a case operated on by the route suggested by Kanavel. There was a large cyst in the hypophysis filled with cholesterin and holding about 1½ to 2 oz. of fluid. Patient made a good recovery after the operation and his vision, which before was extremely poor, has been much benefited.

Dr. Harvey Cushing, of Baltimore: The various means of approach to the hypophysis do not make so much difference as does the matter of dealing with the structure when it is brought into view. The growth often becomes malignant, as is true of long-standing trouble with the thyroid, and it is conceivable that it cannot be entirely removed. In fatal cases it has often been found that only a mere fragment of the growth has been taken away. The operation in the first place has for its object the relief of pressure; these symptoms can be combatted by the mere removal of the lower part of the sella turcica and the splitting of the capsule of the gland. Whether many of these adenomas are merely hypertrophies of the gland, comparable to various diseased changes in the thyroid, we do not know, but if so, partial removal is indicated.

Dr. A. B. Kanavel, of Chicago: Concerning the technical procedure in Dr. Halstead's cases, in the first one particularly, the view could not have been better. The operation was very quickly done, the anterior wall of the sphenoidal sinus quickly removed and the bulging sella turcica opened, and a tumor protruding into the sinus was removed without difficulty. In the second case the sella turcica did not bulge into the sinus; it was seen with more difficulty and was arrived at by anatomical deductions. In two cases there was considerable hemorrhage, and I would suggest the elevation of the head during the operation. In the majority of cases it will only be necessary within the nose to remove the vomer and the anterior portion of the sphenoid in order to come down on the sella turcica.

Dr. Dean Lewis, of Chicago: The tissue removed from the first case contains no elements which are ordinarily found in the anterior lobe or the pars intermedia. The tumor is composed of stratified epithelium with a papillary arrangement. The lower cells rest upon the stroma of the papillæ and are cylindrical, while the cells of the succeeding layers differ in shape, the differences apparently being due to variations in pressure. As the cells of the anterior lobe and the pars intermedia are not reproduced in this growth, we must assume that the tumor has probably developed from an epithelial inclusion, which has not gone on to complete differentiation. The growth corresponds histologically to a group of tumors which occur about the infundibulum and extend down to the sella and up to the third ventricle.

The tissue removed from a second case came from the anterior lobe. In some sections the cell columns are cut parallel, long rows of cells resting between rather thick connective tissue trabeculæ. In other fields the cell columns are larger than normal, the connective tissue between the different columns having broken down, thus permitting of fusion. In still other fields the fusion has become so marked that large groups of cells are found, hyperplasia apparently having ended in adenoma formation. Karyokinetic figures may be seen in a number of different fields.

It is important to recognise the complex structure of the hypophysis in making the anatomic diagnosis of tumors of this gland, and to remember that the cells of the anterior lobe, when growing rapidly, tend to

reproduce the structure of a sarcoma. Stains which differentiate granules should, therefore, be used in the study of all growths apparently originating in the hypophysis.

BENIGN BONE CYSTS, OSTITIS FIBROSA, GIANT-CELL SARCOMA AND BONE ANEURYSM OF THE LONG PIPE BONES. A CLINICAL AND PATHOLOGICAL STUDY, WITH THE CONCLUSION THAT CONSERVATIVE TREATMENT IS JUSTIFIABLE.

JOSEPH C. BLOODGOOD, M.D., of Baltimore, Md.: In many lesions technic is ahead of diagnosis.

The development of technic is more rapid, because the results of faulty technic are immediate, while the development of diagnosis is more difficult, especially in tumors, because the results are more remote.

Treatment of tumors which will assure the patient the greatest possibility of a permanent cure with the least mutilation will only be accomplished when surgeons have a better conception of the local growth of neoplasms, both benign and malignant. This is especially true of the three lesions of the long pipe bones which I wish to present in this contribution.

The so-called benign bone cyst may present itself in five forms: First, as a medullary cyst without any definite gross lining; second, as a similar cyst with a definite connective tissue lining which is easily stripped from the bony capsule; third, as a medullary mass of fibrous tissue with a small cyst; fourth, as the same medullary mass of fibrous tissue without any cyst formation; and, fifth, as multiple medullary cysts.

Among 89 cases, of which 20 were personally observed, 69 belong to the variety of true localized bone cyst or ostitis fibrosa. The other 20 cysts have different etiological factors, for example, cysts in enchondroma, in pure myxoma, in giant-cell sarcoma, in ostitis deformans; cysts due to subperiosteal ossifying hematoma, and callous cysts.

The true benign bone cysts are pathologically identical. In the cases with no definite lining there is found under the microscope between the bone lamellæ of the bony shell the same connective tissue seen in the gross in the other four types. This connective tissue has a definite histological appearance which has been, but should not be, mistaken for spindle-cell sarcoma. In a certain number of cases areas of giant cells are found, but they should not be interpreted as giant-cell sarcoma. Also, one will find, in the gross and with the microscope, islands of cartilage.

At the exploratory incision there is always a thin shell of bone; the contents of the cyst is usually of a dark-brown color and thin; it has never been distinctly hemorrhagic with large blood clots as the contents of the so-called bone aneurysm. The character of the fluid and the gross appearance of the fibrous tissue should allow one to differentiate this lesion, whether it appears as a cyst or a completely solid area. This lesion has been and can be cured by simple incision and curetting. It is distinctly benign, and from an experience over many years with sixty-nine cases it has shown no tendency to malignancy.

The giant-cell sarcoma, of which I have studied personally nineteen cases, can also be recognized at the exploratory incision. The medullary cavity is filled with a soft, hemorrhagic tissue resembling granulation tissue mixed with whitish areas which, when removed with the curette, come away in masses of irregular shape. This tumor also has been cured by curetting. It is eight years since I curetted from the medullary cavity of the upper end of the tibia such a tumor, and this patient has no evidence of recurrence to-day. Among my personally studied cases, and in the literature, I have so far been unable to find metastasis from a giant-cell sarcoma. Cases have been cured even after repeated curetting; amputation is only indicated when the patient has allowed the tumor to grow to such a size that it has perforated the bone capsule and infiltrated the soft parts to such an extent that its complete removal would leave a functionless limb. Even in such cases I believe it will be justifiable to first attempt curetting, use the Paquelin cautery, followed by x-ray treatment. But such extensive cases are unusual. The point that I wish to emphasize is that giant-cell sarcoma can and should be recognized at the exploratory incision, and in the majority of cases an attempt should be made to cure the disease with the curette.

The so-called bone aneurysm is a much less frequent tumor. It is distinctly malignant. It is a hematoma due to hemorrhage in the most malignant form of medullary spindle, round or mixed-cell sarcoma, and I am of the opinion that in this stage of this tumor metastasis has already taken place, so that no harm could come from mistaking such a tumor for a bone cyst or giant-cell sarcoma. I have seen 3 cases. In 2 the diagnosis was not difficult, one patient was not saved by the highest amputation; in the second case amputation was refused; the third case was first treated as bone cyst; amputation was done later, but the patient died of metastasis.

DISCUSSION.

DR. RUDOLPH MATAS, of New Orleans: I would call attention to a case in which, after removal of a giant-cell sarcoma from the humerus, there was such a large cavity that I used about 1½ oz. of mosetic cement, and the patient later developed extreme symptoms of iodoform poisoning, as was but natural from the large amount of the cement used. In ten days, however, he recovered from its effects and the arm healed with a perfect contour of the bone. I believe that in Beck's paste we have a most valuable means of filling up cavities, it being superior in my mind to any other paste.

DR. WILLIAM L. RODMAN, of Philadelphia: I recall a case operated upon in 1889 for large giant-cell sarcoma of the lower jaw by free chiselling and curettement, but without removal of the maxilla. The patient lived for more than ten years after this operation, and may be alive to-day.

DR. JOSEPH A. BLAKE, of New York: I had a case of sarcoma of the bone, the fourth finger of the patient being diseased. A simple operation in this case proved most satisfactory, and now, three years since operation, there is a normal phalanx.

DR. HARRY M. SHERMAN, of San Francisco: I would say that in my experience salt solution poured into these cavities a little in excess just before the last stitches are taken is as good as any other material for filling; it is replaced by blood and obviates the necessity of putting in any foreign body such as iodoform or bismuth.

DR. DUDLEY P. ALLEN, of Cleveland: Some years ago I removed the lower jaw of a patient for giant-cell sarcoma, leaving but a small portion of the substance of the jaw. I used a splint to hold the teeth in place. The patient recovered entirely and is now well.

DR. WILLIAM S. HALSTED, of Baltimore: I am reminded of a patient with a myxoma of the humerus; although the disease involved the bone from one end to the other, there was no cyst and no fibrous tissue. The bone was excised excepting for a strip posteriorly and at the lower end, and the entire cavity carefully swabbed out with carbolic acid. The patient made a good recovery and had a strong humerus, but there were implantation recurrences in the soft parts on two occasions. It has now been four years since the first operation, and the patient at present is perfectly well.

Dr. Nathan Jacobson, of Syracuse: In reference to giant-cell sarcoma of the jaw, I recall one case still living in whom I did a partial excision of the upper jaw for giant-cell sarcoma about twenty-five years ago. There was never any recurrence. In my experience in those cases of giant-cell sarcoma where there is reasonable cleaning out, there is seldom a recurrence of the growth.

Prof. A. von Eiselsberg, of Vienna: In such cases as these mentioned by the reader of this paper we are in the habit, before finishing the operation, of pouring boiling water into the wound in order to destroy all the germs, and have found it a most satisfactory method.

Dr. Joseph C. Bloodgood, of Baltimore (in closing): Dr. Halsted's case of exostosis with involvement of the humerus brings out the point that pure myxoma is a benign tumor, that recurrence after operation may be due not so much to leaving a portion of the tumor growth behind as to infecting the wound in removal of the tumor. In such cases it would be well to use boiling water, pure carbolic or Paquelin's cautery to disinfect the wound.

DIAGNOSIS AND SURGICAL TREATMENT OF ESOPHAGEAL DIVERTICULA.

Charles H. Mayo, A.M., M.D., of Rochester, Minn.: Diverticula of the esophagus, described by Rokitansky in 1840 and classified as *pressure* or *pulsion* sacs, and traction sacs. Most cases are pharyngo-esophageal, determined by the origin of the diverticulum.

The condition is confined to adults. Dysphagia is the most common symptom; cough and dyspnea are common. Distended sacs are often visible in the neck, and can be emptied by pressure. Condition is disclosed by probing and by radiograph of bismuth-distended sac.

H. S. Plummer's method of diagnosis is a combination of the technic of Mixter and Dunham, as used in stricture. The patient swallows a silk thread which passes into the intestine. The Plummer perforated acorn probe passed on the thread gives depth of pocket and location of its neck. By alternating the tension of the thread, elevating the probe to the distal opening of the esophagus, a pocket and its depth can be ascertained and tubes passed for feeding. Gastrostomy for temporary feeding may be necessary.

Operation is as follows: Lateral oblique incision; blunt dissection; exposure of sac and excision; closure by suture; rubber tissue drain.

There have been 8 cases in the Rochester clinic; 6 operated upon successfully and 2 which were not operated upon.

REMOVAL OF A TACK FROM THE LEFT BRONCHUS.

N. B. Carson, M.D., of St. Louis, Mo.: Annie Y., aged four, came to my service in the St. Louis Mullanphy Hospital Jan. 18, 1909. All that could be learned was that a month before entering the hospital she was supposed to have swallowed an upholsterer's tack, which was followed by a severe spell of coughing, and later by a very serious illness. Physical examination showed the child to be very pale, anemic, emaciated and weak. She swallowed either liquids or solids with difficulty, and coughed almost constantly, with an expectoration of white mucus, and the coughing was accompanied by a very severe pain on the left side of the sternum. The left lung was dull in the middle portion, while the upper and lower portions were more or less resonant.

A skiagraph of the chest showed the tack in the median line with the head down, and the point upwards, the point being lodged in front of the body of the fifth dorsal vertebra. Examination of the sputum was negative, as was also Von Pirquet's test.

On Jan. 27 tracheotomy was done, and an attempt made by means of the bronchoscope to remove the tack, which failed. On Jan. 29 a skiagraph located the tack about the beginning of the left bronchus. Jan. 30, under rectal anesthesia, a section of about an inch of the seventh rib on the posterior axillary line was removed, and an opening made into a small abscess cavity in the lung, which discharged about an ounce of yellowish pus. At the same time the bronchoscope was reintroduced into the tracheal opening, and the left bronchus was found to be entirely closed. On account of the inability to get permission to operate sooner, nothing was done until the 27th of July, when an opening was made in the chest over the sixth rib and about three inches of the rib removed, and the pleural cavity opened. The lung was entirely solidified, and upon exploring the left bronchus at its entrance into the base of the lung an abscess cavity was located which when opened discharged about a dram of fetid pus. The tack was found in this abscess cavity and removed.

At 7.30 of the same evening there was a twitching of the left side of the face, arm and hand, which was followed by a partial hemiplegia. After this the patient improved steadily until the evening of Aug. 2, when there was a gush of blood from the nose and mouth which was speedily followed by death. Post-mortem showed that there had been an extensive inflammation involving the entire lung and the pleura of that side. Between the left bronchus and the pulmonary artery was an abscess cavity in which the tack had been lodged after it had forced its way through the bronchus. A small opening was found in the pulmonary artery as a result of the erosion caused by the head of the tack.

DISCUSSION.

Dr. Samuel J. Mixter, of Boston: I have operated upon three cases of esophageal diverticula. Where operation is not done by the passage of very large bougies or probangs by means of a string guide, a sufficient dilatation of the spur can be caused to allow the passage of food, and food sufficient to keep the patient alive. I have about half a dozen such cases now.

Dr. George W. Crile, of Cleveland: I wish to record two cases of operation for esophageal diverticula, both of which recovered.

Dr. John B. Murphy, of Chicago: The enucleation of the sacs of diverticula is not a difficult matter in itself, but it leaves a large cavity, and it is difficult to avoid the danger occurring from leakage at the suture, infection from the mouth and particularly the action of the salivary glands upon the loose connective tissue of the mediastinum. I believe not opening the sac at all is the only safe procedure.

With reference to foreign bodies in the bronchus, I think more care should be taken to corroborate the history in such cases, as not infrequently on operation no foreign body is found, but some pathological condition which accounts for the symptoms.

Dr. George E. Brewer, of New York: I would call attention to one symptom in esophageal diverticula which is characteristic, that is, the presence frequently during the day, perhaps every hour or half hour, of an accumulation of thick, tenacious mucus which the patient will regurgitate to get relief. My own experience has been limited to 3 cases and 1 operation. This patient was a woman eighty years of age who had lost 50 lb. through starvation. She made a perfectly good recovery from the operation.

Dr. De Forest Willard, of Philadelphia: Surgeons should always remember the possibility of enlarged thymus in sudden deaths in young infants under ether. In such cases one is very likely to be misled by the

statement that the child has swallowed some foreign body.

DR. WILLIAM L. RODMAN, of Philadelphia: I believe in cases of foreign bodies in the air passages great risk is incurred in delaying the period of operation, and would urge that all such cases be operated upon immediately upon being seen.

DR. NATHAN JACOBSON, of Syracuse: I simply wish to refer to one case of a fifteen months' old child who swallowed a bean. By a tracheotomy the bean was gradually removed and the child made a good recovery. Regarding misleading histories, I was called to see a child suffering from complete obstruction of the trachea. I was told he had swallowed a piece of bone. Subsequent history showed, however, that the child had inherited syphilis, and evidently had gradually increasing disturbance, and the history of the swallowing of the foreign body was purely an assumption.

DR. ALBERT VANDER VEER, of Albany: With reference to esophageal diverticula, I would like to mention two cases, one in a physician who refused to have an instrument passed and who subsequently died of an acute pneumonia; the other occurring in a woman about fifty years of age. In this case it was impossible to get into the stomach with any form of instrument, and I, therefore, did a gastrostomy and the patient made a splendid recovery. She now alternates between tube feeding and the natural method.

In regard to foreign bodies in the bronchi and in the air passages, I wish to urge that the bronchoscope be made the last resort in such cases and only be employed in the hands of experienced and careful men.

DR. JOSEPH RANSOHOFF, of Cincinnati: I had a very interesting case of abscess of the lung living four or five weeks after operation, the result of the inhalation of a peanut shell.

I would like to mention a case of a foreign body in the air passages which was unsuspected. Some two or three months after doing an intubation for laryngeal croup in a little child, the patient expectorated a small triangular tag such as is used to stiffen the corners of pasteboard boxes; the presence of this foreign body had not been suspected at the time of operation.

DR. N. B. CARSON, of St. Louis (in closing): I cannot too strongly urge the observance of the rule that the bronchoscope should only be used by competent and skillful men. I consider it a dangerous instrument when generally used.

SOME OBSERVATIONS REGARDING THORACIC SURGERY ON HUMAN BEINGS.

WILLY MEYER, M.D., of New York, N. Y.: Dr. Meyer has so far operated upon 10 cases with the help of his differential pressure apparatus for affections of the pleura, lung and esophagus. After discussing the effect of differential pressure, in more rapidly bringing to a close the empyema cavity, as well as its usefulness in the after-treatment, he dwells particularly on the cases of two young patients, six and eleven years old respectively, who had suffered for years from bronchiectatic abscess symptoms; both were bad risks. He extirpated a lobe of the lung in each case, but neither recovered.

Three times exploratory thoracotomy was done for cancer of the esophagus, with recovery. In order to do good surgical work when operating for a malignant stricture of the esophagus, he found it necessary to get the scapula out of the way. He, therefore, proposes as a preliminary operation the Schede-Friedrich flap operation, by which the entire shoulder girdle is turned up, thus permitting the surgeon to make his incision into the thoracic cavity wherever required; often two incisions are necessary. Dr. Meyer prefers the intercostal incision to resection of the rib or ribs. He presented illustrations which demonstrated the procedure.

On March 31, 1910, Dr. Meyer for the first time proceeded in this way for a cancer of the esophagus in a patient forty-three years of age. It was found that the malignant tumor extended from about 1½ inches above the cardia to the aortic arch. After division of the esophagus and inversion of the lower stump through the sixth intercostal, the third interspace was opened and the healthy portion of esophagus reached, outside of the common carotid artery, after proper division of the costal pleura; then the entire diseased portion was shelled out and brought in front of the aortic arch. To the operator's dismay it was found in the course of this latter part of the operation that the growth involved the right pneumogastric nerve; it was impossible to push the nerve off; it had to be divided at the lower end of the tumor, and again interfered with in amputating the esophagus above the upper border of the tumor. The proximal end was also inverted by a double purse-string suture, the intention being to do gastrostomy two or three days later. The interference with the pneumogastric nerve had a deleterious effect upon the heart action, which up to this time had been splendid. The operation was well completed, but in spite of intravenous infusion given, the patient succumbed shortly afterward.

It is pointed out that the only hope of operative success in these cases lies in *early* operation, certainly before the intimately adjacent pneumogastric branches are involved, and the first step of such operation should be to prepare free these nerves. Their involvement will more or less decide the operability or inoperability of the given case.

Additional experimental work is required in order to determine how far we are permitted to divide the pneumogastric on one side of the esophagus should the growth within the latter have encroached upon the nerve. Involvement of the nerve on either side is an absolute contra-indication to going ahead with the operation. Interference with the pneumogastrics during the operation greatly affects the heart's action as well as the respiration. The ordinary stimulants, inclusive of intravenous infusion, are of no avail. Sudden changes in differential pressure, however, have been found of great value. The author briefly discussed how best to carry out in such emergency artificial respiration, which he is able to do also with his differential pressure apparatus.

Up to the present time resection of the esophagus has a mortality of 100%.

END-TO-END INTESTINAL ANASTOMOSIS BY THE INVAGINATION METHOD.

C. L. GIBSON, M.D., of New York, N. Y.: End-to-end intestinal anastomosis by telescoping one segment into the other has been practised from time immemorial, but at present has no recognized position in surgery. As a result of animal experiments and 5 successful cases the author believes that with his present technic it furnishes a method for which there is a demand, particularly in the surgery of the lower end of the colon. The technic is as follows:

The upper cut edge of the gut is seized with two Kocher clamps and introduced by these into the lumen of the lower end and maintained there by an assistant. The extent to which it is feasible to accomplish this invagination will vary. The gut is rotated about a quarter circle so that the non-peritoneal covered surfaces do not entirely approximate in the circumference. Eight to twelve interrupted silk sutures are introduced thus. A Lembert suture is begun on the lower segment,

the needle issuing just short of the cut edge, on the upper segment the needle is introduced just above the line where the cut edge of the lower segment lies against the intact wall of the upper. When the knot is tied, the free cut edge has been turned inward and only the peritoneal surfaces are in contact. A continuous running suture is applied over this area, further invaginating the first ones, the Kocher clamps being previously withdrawn.

POST-OPERATIVE INTESTINAL OBSTRUCTION.

GEORGE WOOLSEY, M.D., of New York, N. Y.: *Importance of subject.*—Common occurrence by reason of frequency of abdominal operations, in spite of improved technic. Frequency of septic or paralytic cases much reduced by improved technic. Fifty cases collected in past five years in the Presbyterian Hospital, only 6 of these paralytic obstruction, 9 due to strangulation, 2 to volvulus, and most of the remainder to angulation. Nine of these in my service (mortality 12.5% in 8 operations). An equal number in practice elsewhere.

Classification.—Early and late (Broca), mechanical and dynamic (Mikulicz). Mechanical ileus comprises strangulation and obturation. Dynamic, or, better, paralytic, obstruction, most often due to sepsis, some cases due to post-operative atony, others to disturbance of innervation.

Etiology. — Two great factors, septic and mechanical.

A. Mechanical.—(*a*) Strangulation, usually due to band or volvulus, or both. When blood supply cut off, paralysis of gut is added. (*b*) Obturation commonly depends on angulation. Distended proximal arm of loop presses on distal arm and closes it like a trap, the adhesion of the end of the loop preventing it from being straightened out by peristalsis. Adhesions most often in or near pelvis. Most adhesions disappear in time. Factors determining obstruction by adhesions: (*a*) Adhesions of gut in an abnormal position; (*b*) idiosyncrasy to the formation of many and firm adhesions. Other causes of mechanical obstruction: (*a*) Secondary abscess, causing pressure and usually a valve-like closure, as in cases of adhesions; (*b*) Trendelenburg position; (*c*) pressure of root of mesentery on duodenum, causing arterio-mesenteric ileus or acute dilatation of the stomach.

B. Paralytic obstruction. — A similar result (paralysis) due to (*a*) sepsis, the most common cause; (*b*) handling of intestine causing atony, or (*c*) to trauma of nerve supply, as in extraperitoneal operations, etc. Sepsis probably acts mostly by a reflex paralysis on Auerbach's plexus. Peristalsis may be reflexly inhibited through splanchnic nerves (Cannon and Murphy). Overdistention may arise from the atony due to handling or traumatism of nerves or plexus. Overdistention may cause obstruction by causing (*a*) paralysis, (*b*) angulation, (*c*) volvulus.

Obstruction most often follows appendicitis or appendectomy (32 in 50), next most often pelvic conditions (13 in 50), especially ovarian cysts. Mortality of the 50 cases (48 operations), 37.2%.

Pathology of fatal result. Death due to bacteriemia in septic peritonitis. Where no peritonitis, death attributed to auto-intoxication (neurin, putrescin, etc.). Braun denies this and claims terminal sinking of blood pressure due to basal anemia from great blood stasis in splanchnic area, and that drainage of bowel favors cure by relieving congestion in splanchnic area, not by avoiding auto-intoxication. Several experiments confirm this.

Diagnosis easy from symptoms in late cases. If morphine has to be repeated for pain, operate for obstruction. In many cases we can distinguish between strangulation and obturation by "peritoneal shock," intensity of onset and symptoms. In some cases we can locate position of obstruction by position of early pain, distention, exaggerated peristalsis, character and onset of vomiting, Von Wahl's sign, etc.

In *early cases* diagnosis not so easy, obscured by peritonitis, operative trauma, sequelæ of anesthesia. Where peritonitis was or is present, must distinguish between it and obstruction. Many of the symptoms identical. Diagnostic symptoms given. Rigidity the important sign of peritonitis; absolute constipation, of obstruction. If latter cannot be relieved, diagnose obstruction. Some early causes of mechanical origin. Important but difficult to distinguish them. Presence or absence of pain, peristalsis, distention and other signs help to determine question. Possibility of acute dilatation of stomach (symptoms enumerated), and of obstruction with many symptoms lacking must be remembered.

Treatment.—*A.* Prophylaxis, great importance and success of it. Problem is to prevent sepsis, operative trauma and adhesions, to which nearly all cases are due. Hence operate all cases of appendicitis as soon as diagnosis is made. When septic peritonitis present, modern technic (Murphy's) will cure most cases and prevent paralytic ileus. Opposite plan advocated by some, i. e., excitation of peristalsis to distribute germs, increase hyperemia of peritoneum and thereby the autolysis and resorption of the pus. Physostigmine or atropine used by some before and after operation. The real field for this is in post-operative atony. To prevent the atony, avoid rough and undue handling of intestines. When early distention is marked and increasing, gain early action of bowels by enemata of various kinds, with or without physostigmine. Stupes and lavage also very useful. Careful post-operative treatment of diet, digestion and bowel movement very essential prophylactically.

Adhesions a prolific source of obstruction. Can we prevent them? Not altogether. It is largely a matter of careful technic. Operate early, rapidly, yet carefully; avoid drainage. If drains necessary, the kind of drains and their position of great importance. Remove source of infection, avoid displacing of bowels, cover denuded peritoneum if possible, encourage early peristalsis and frequent change of position after operation. Can we prevent the re-formation of adhesions? No, we may minimize them. Great variety of substance interposes between raw surfaces. No one a panacea. Many enumerated. Mucilage apparently the best.

Treatment of actual obstructions is *operative*.

Late obstructions. — Ample incision over site of obstruction if known, otherwise exploratory. Operate early. Collapsed and distended coils guides to obstruction. Relieve cause. If gut not viable, resect and anastomose.

Early obstructions. — Palliation by enemata, physostigmine, lavage, etc., should not be persisted in too long. Most cases operated too late. If mechanical cause suspected, laparotomy and relief of cause. If paralytic obstruction, enterostomy with flushing and syphonage. Technic of enterostomy. Objections to enterostomy. It should be done earlier to avoid the present poor results. In the early obstructions prophylaxis has given best results and made them much less frequent.

DISCUSSION.

DR. CHARLES H. MAYO, of Rochester, Minn.: I want to testify to the invagination method being a good one in the removal of tumors low in the sigmoid, at the upper rectum; in fact, it is about the only way you can

get a union, — to invaginate the upper end into the lower.

DR. JOHN B. DEAVER, of Philadelphia: I wish to report the following cases in this regard. The first is as follows: In the early part of last winter an artificial anus caused by ulcerative separation of the lower sigmoid at junction with rectum, due to pressure necrosis consequent upon the presence of an old appendiceal abscess, evacuated through the linea alba some weeks previously. Spencer Wells forceps passed up rectum and sigmoid brought down to anus and stitched to freshened margin of anus. Patient made a good recovery. The second case occurred three weeks ago, being one in which the lower sigmoid was damaged in removal, by pan-hysterectomy, of a uterine tumor involving the bowel. Patient recovered.

DR. ALBERT J. OCHSNER, of Chicago: If immediately upon the appearance of nausea or gaseous distention gastric lavage be instituted, there will be fewer instances of intestinal obstruction following shortly after operation. As regards intestinal obstruction due to conditions appearing many weeks after operation, our observation has been that we have practically no mortality excepting in those cases coming under our treatment after having received cathartics.

DR. E. WYLLYS ANDREWS, of Chicago: End-to-end anastomosis implies for success that we get our lumen at once, and this is not true with the McGraw ligature; but if we can devise a method by which all the advantages of this ligature can be strengthened by obtaining the open lumen immediately, we will have an ideal method.

DR. ALEXANDER H. FERGUSON, of Chicago: In regard to operative obstruction and the prevention of adhesions following operations, I would say that for four years I have used subgalate of bismuth, smearing it over all raw surfaces, with most complete satisfaction.

DR. ARPAD G. GERSTER, of New York: If we want to make headway against obstructions caused by adhesions, we must first know the cause of the adhesions, and this we do not know at present. Many causes have been exploited, the use of packings, the handling of the intestines and other mostly traumatic lesions to the peritoneal coat, but we have seen in the presence of the greatest traumatism that could be inflicted on the intestine that adhesions did not form. Here the pathologist and experimental surgeon must come to our aid. I believe that the cause must be looked for in certain conditions of the blood of the patient.

ABNORMAL POSITION OF THE DUODENUM.

G. E. ARMSTRONG, M.D., of Montreal, Canada: The duodenum is singularly constant in its relations, course and length; any exceptions are exceedingly rare and worthy of note.

In the anomaly reported, the duodenum ran to the right and then turned downwards external to the hepatic flexure, ascending colon and cecum, and, merging into the jejunum, passed from without inwards below the cecum into the small intestine area. The duodenum was completely surrounded by peritoneum. It had a long mesentery throughout and could easily be held two or three inches in front of the abdominal wall. The head of the pancreas, closely applied to the duodenum, was visible and palpable between the layers of the duodenal mesentery, and readily followed the duodenum when the latter was brought outside the body.

Instead, therefore, of passing across the second lumbar vertebra and behind the transverse colon and superior mesenteric artery, it retained an early embryological position. There was, of course, no ligament of Treitz and no fossa duodeno-jejunalis. The condition is clearly one of arrested development. The cecum in this case did not mount upwards to the lower hypochondrium and did not pass in front of the loop of the duodenum. The cecum did not descend to its usual final resting place in the right iliac fossa. It was high, completely surrounded by peritoneum, very movable and could be brought out through the epigastric incision and held eight inches in front of the body.

DISCUSSION.

DR. MAURICE H. RICHARDSON, of Boston: I would report a case in which the appendix, the gall bladder, the liver and the ileocecal valve were on the left side, the spleen on the right side, and the heart on the right side.

DR. EMMET RIXFORD, of San Francisco: I would like to put on record a case of failure of rotation of the primary gut. The explanation of this condition is probably to be explained on the basis of adhesions of the cecum to the parietal peritoneum, the result of a fetal peritonitis.

DR. LEONARD FREEMAN, of Denver: I had a case in which acute dilatation of the stomach followed an unimportant pelvic operation, and which at autopsy showed the duodenum passing directly beneath the liver and firmly attached to the posterior abdominal wall and around the right side as far as the hepatic flexure of the colon.

DR. JOSEPH A. BLAKE, of New York: I have met with two cases of abnormal position of the duodenum in my practice. I do not think there is apt to be dilatation in such cases, as the mesenteric vessels do not cross the duodenum, and the duodenum, instead of being bound down, is usually free.

DR. ALEXANDER PRIMROSE, of Toronto: I would like to emphasize the fact that these conditions of abnormality in the position of the duodenum may occur without giving rise to the slightest symptoms.

DR. JOSEPH C. BLOODGOOD, of Baltimore: I would like to record one other anomaly of the intestinal tract which I think must be very unusual, namely, absence of the appendix.

(To be continued.)

Book Review.

Diseases of Infancy and Childhood. Their Dietetic, Hygienic, and Medical Treatment. A Text-Book Designed for Practitioners and Students in Medicine. By LOUIS FISCHER, M.D., Attending Physician to the Willard Parker and Riverside Hospitals; Attending Pediatrist to the Sydenham Hospital, etc. Third edition. Pp. 980. Three hundred and three illustrations several in colors, and twenty-nine full-page half-tone and color plates. Philadelphia: F. A. Davis Co. 1910.

This, the third edition of this well-known work, has been thoroughly revised and enlarged, but, as before, the work is far from being a satisfactory one. It is badly arranged, some conditions being given far more attention that they deserve, and others being slighted. It contains a great deal of valuable information very poorly classified. While, of course, a useful book, it is far inferior to several other American textbooks on the same subject.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, OCTOBER 13, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

SOME PUBLIC ABOMINATIONS.

ATTENTION has recently been called in the daily press to the non-enforcement of our law against spitting in public places. The evils of promiscuous expectoration are sufficiently obvious to need no comment. The trouble is that there is not yet a sufficient public sentiment against spitting to compel its discontinuance. There is something in the irresponsible and defiant lawlessness of the habit which makes it appeal to the undisciplined independence of the American temperament. The wilful spitter, — and most offenders are of this class, — by the act proclaims his contemptuous disregard of others, like the upstart millionaire who boasted, on returning from his travels, that he had spit tobacco-juice on the floor of every palace in Europe. Spitting is a public abomination, an offense against hygiene, against decency, against good manners; but it will not be abolished from among us until education leads people to realize its vulgarity as well as its dangers.

A further evidence of the slowness with which real civilization progresses may be observed in the common drinking cup, whose banishment we have only just essayed, and to which many persons still cling with the blind obstinacy of Ephraim wedded to his idols. Nothing in the world dies so hard as a fetish, or so easily as the people whom it kills. The common roller-towel is another abomination whose abolition should go hand in hand with that of the public drinking-cup. One reason for its continued persistence is the expense of laundering many individual towels. Recent report from Milwaukee states that the Board of Education in that immaculate and famous city has adopted, for use in the public schools, individual paper towels, which are very cheap and are intended to be used once and then burned. This substitute seems satisfactory and worthy of general adoption. In the matter of towels, however, we may at least flatter ourselves that we are even now a step in advance of Europe, where in every lavatory the towel that hangs upon the wall, far from soap and water, suggests possibilities of uncleanliness and disseminated infection almost too disgusting for even a physician to contemplate.

Such observations on the "ways and works of man" are enough to show that in some respects he is still "very little changed from the semi-apes." Perhaps, indeed, it was a dubious compliment to call him "the paragon of animals." Howbeit, it were better to look on the other side of the picture and reflect that we have already begun the relegation of these abominations to the limbo of outgrown infirmities. If the habit of spitting be in our community

> "The dram of eale
> Which doth the noble substance often dout
> To his own scandal,"

its abolition should be one of the desiderata which Boston may hope to attain in its approaching year of perfection.

CHOLERA SITUATION.

THE European epidemic of Asiatic cholera has continued with little change during the past week. In Russia conditions are as bad as ever. Genuine efforts are, no doubt, made by the government to combat the disease, but these are to a great extent thwarted by the ignorance and superstition of the peasantry, who, believing that the cholera is an evil spirit that can be appeased only by having his glut of victims, refuse all aid and instruction, mob the doctors, nurses and sanitary officials, and persist in drinking polluted water and in disregarding all measures for the prevention of infection. Moreover, the primitive hygienic provisions prevailing in many parts of Russia make such measures largely unavailing. Of the 762 cities of European Russia, it is stated that only 149 have a municipal water-supply and only 27 any system of drainage. Under such circumstances it is no wonder that the people die like flies. It is estimated that in the past six weeks alone there have been, in Russia, 150,000 cases and 75,000 deaths of cholera.

In Italy, where the epidemic is on a smaller scale and should be much more controllable, there seems little sign of cessation of the disease. The

record of incidence and mortality for the week of Oct. 1 to 8, as nearly as can be learned from available reports, is as follows: In the city of Naples, 54 new cases and 24 deaths; in the province of Naples, exclusive of the city, 43 cases and 13 deaths; in Apulia, 3 cases and 3 deaths; in the province of Sassari, 2 cases; at Torre del Greco, 1 death; and in the provinces of Avellino, Bari and Casserta, 12 cases and 5 deaths. The disease has also appeared in the island of Sardinia, where 4 cases and 1 death were reported on Oct. 3. As yet the infection has not invaded France, though 3 cases were found on board the steamer *Bosphore* in port at Marseilles.

In the United States, stringent precautions to prevent introduction of the disease continue to be observed. Every immigrant from an infected port is detained five days under quarantine before sailing and every steerage passenger five days on arrival. These measures have resulted in the detection of several suspicious cases, three of which in New York appear to have proved to be genuine Asiatic cholera. One of these patients has since died; the two others at latest accounts are still in the Swinburne Island Hospital. The rigor with which these precautions are enforced has aroused protest from the Italian government, which objects also to our inspection of merchandise and foodstuffs for exportation to the United States from infected districts. Our government has, however, not yet thought it necessary to lay an embargo on such goods. Notwithstanding, the United States Public Health and Marine-Hospital Service has doubled its detail of officers on duty at every port in Russia, Italy and Germany from which emigrants sail in large numbers. These measures need excite no popular apprehension in this country; they are merely evidence of the vigilance which constitutes our safety. The same is true of the meeting of the Advisory Public Health Board, called in Washington on Oct. 10, presumably to consider the cholera situation. We have as yet no report of the action of this meeting, but there is no reason to regard its convocation as evidence of particular danger. Our health officials are zealous and intelligent, and intelligence and zeal afford ample protection against such a disease as Asiatic cholera.

DANGERS OF SCANTY WATER SUPPLY.

In spite of the statement recently made that the water-supply of Boston is sufficient to last for nine months in the entire absence of rainfall, it remains true that a long-continued drought, like that of the past summer, seriously reduces the quantity and may impair the quality of the water-supply of smaller cities and towns less fortunately circumstanced. It is reported, for instance, from Palmer, Mass., that of the three reservoirs used by that city, two are dry and the third very low. An engineer sent by the Massachusetts State Board of Health to inspect these reservoirs is said to have reported on Oct. 6 that, owing to exposure of their shores, the condition of the remaining water is such as to render it unsafe for drinking unless boiled. There is now barely sufficient water for drinking and bathing, and not enough to fight a serious fire, should such occur.

The importance of adequate and pure water-supply for the health and safety of a community is self-evident. Moreover, as emphasized by the recent statistics of Sedgwick and MacNutt in the *Journal of Infectious Diseases* [reviewed in this JOURNAL, vol. clxiii, p. 524], there is a much less obvious but none the less apparently definite relation between purity of supply and the incidence of diseases not commonly thought of as water-borne. The causes on which this relation is based are not yet clearly understood, and the morbidity statistics of Palmer for the current and succeeding year might reasonably be expected to throw interesting light on the question. Meantime it is desirable that not only Palmer, but other cities similarly situated, should make every effort to secure a water-supply which shall guarantee them from recurrence of the present unfortunate conditions.

CHOLERA THEN AND NOW.

WHEN, in 1892, the news came that cholera had entered the port of New York, something like a general panic resulted. "Flustered officials, state and municipal," to quote a lively description of the state of affairs, "rushed into action in such haste that the measures they took came near starting a little war. Indeed, soldiers, or near-soldiers, of various sorts had to be ordered out to enforce the governor's orders, and a lot of money was spent for beach land with which nothing was ever done." Now, by reason of the progress which has been made in sanitary science since then, and the reliance on its protective efficiency, a similar announcement has been received by the authorities and the public with perfect composure. On the steamer *Sant' Anna*, of the Fabre Line, which arrived recently from Europe, a steerage passen-

ger died from cholera during the voyage and was buried at sea, and on Oct. 4, Health Officer Doty made public the fact that one suspect who arrived on Sept. 26 on the steamer *Germania*, also from Italian ports, had died from the disease three days later. Six of the passengers on the *Germania* who were reported in the ship surgeon's journal as having applied for treatment for minor troubles, but were well on arrival, were removed to Swinburne Island for observation. Two days later one of these, a Greek aged twenty-eight years, was taken ill again, twenty-four hours afterwards he was in a condition of collapse, and in twelve hours more he died. In commenting on this case Dr. Doty has made the following interesting statement: "Although the autopsy showed no evidence of cholera, the examination of the secretions of the intestinal tract showed the presence of suspicious organisms. Specimens were sent to Dr. Wm. H. Park, of the Health Department of this city, and to Dr. Anderson, the bacteriologist of the United States Marine-Hospital Service, and the results indicated that the patient died of cholera. This is a practical demonstration of what is known as 'cholera carrier'; that is, persons who may carry organisms of the disease without any symptoms to indicate its presence. In this case it was demonstrated that the extreme precautions taken were fully justified. As the *Germania* case gave practical proof of the fact of 'cholera carriers,' it indicates that in the future additional measures must be put in force." On Oct. 6 it was announced that a coal trimmer on the steamer *Moltke*, which arrived on the 5th, was suffering from genuine Asiatic cholera, as shown by the bacterial examination. This was a comparatively mild case, and the latest reports are to the effect that the patient is in a fair way to recover.

THE BOSTON HOSPITAL SCHOOL.

It was recently voted by the trustees of the Boston Consumptives' Hospital to close the Hospital School maintained by the city at Franklin Park. A committee appointed by the Boston Association for the Relief and Control of Tuberculosis to investigate the value of this school has reported unanimously in favor of its continuance, and in a letter to the mayor the Association strongly urges reconsideration of the action of the trustees. The committee finds that, of 161 tuberculous children who have been sent to the Hospital School, 51 have been discharged, of whom 35 have been returned to the public schools, 28 with their disease arrested or improved. Moreover, the children, while in the Hospital School, have not only benefited in health, but have shown as good progress in studies as those in the regular schools. The committee, therefore, believes that the Hospital School is of value not only for the good it does to individual children, but as an educational agency and a means of gaining the confidence of the public in municipal efforts for the relief and control of tuberculosis.

The work of such an institution is an object lesson in the possibilities of intelligent treatment. Accordingly the association recommends that the Boston Hospital School be not discontinued, and that the trustees of the Consumptives' Hospital build and maintain, in addition, a cottage sanatorium at Mattapan for such tuberculous children as are too sick to attend the Hospital School, or who are mentally defective.

It is sincerely to be hoped that this counsel of experts will be heeded. The success of the Massachusetts Hospital School at Canton might be cited as additional evidence of the possibilities of such institutions, and as argument against the closing of the Boston school. Education and early treatment are the two essentials of ultimate victory in the campaign against tuberculosis, and nowhere can these be better combined than in such an institution as the Boston Hospital School.

PSYCHOLOGY FOR PHYSICIANS.

Under the auspices of the Harvard University Extension Course it is proposed to offer work in psychology under the direction of Prof. Robert M. Yerkes, of the Psychological Department of the University, the course to be an introduction to the study of the principles, methods and values of the science of mental life. The prospectus announces the course as follows:

"The primary aim of the course is to acquaint each student with his own mental life and to arouse interest in the observation of individual mental traits and tendencies.

"By means of lectures, demonstration experiments, conferences, reading and written exercises students in this course are introduced to the study of consciousness. The lectures and demonstration experiments together serve to exhibit the characteristics of the materials, aims, methods and values of psychology. From them the student should gain a knowledge of the chief facts and laws of mental life and an intelligent appreciation of scientific method. The conferences and exercises are planned as aids to the acquisition of the introspective attitude and the development

of skill in self-observation. It is essential that every beginner in psychology should learn to study consciousness for himself."

In view of certain definite and, we believe, highly salutary tendencies in present-day medicine, it is altogether desirable that medical students should have a much more definite knowledge of the laws of mental life than is at present obtainable in any of our medical schools. Opinions may differ as to the desirability of prescribing such courses in the already overcrowded medical curriculum, but certain students whose interest lies essentially in disorders of the nervous system, and in the field of mental disease in particular, should have an opportunity, while pursuing their medical studies, to acquire such psychological knowledge. This University Extension Course offered by Professor Yerkes is admirably adapted to this end and should certainly receive the support of students interested in the difficult and important problems now before the medical profession relating to the nervous system and the mind.

MEDICAL NOTES.

THE COST OF RADIUM. — Report from London states that the present market price of radium is at a rate representing a cost of $2,100,000 an ounce.

YELLOW FEVER IN MEXICO. — It is reported that yellow fever has again broken out in Mexico, and there are said to have been two deaths from the disease at Campeche during the past week.

DEATH OF A FORMER ARMY NURSE. — Mrs. John Mason Loomis, a former army nurse, who died at Chicago on Oct. 7, was born in Shelburne, N. Y., on Aug. 15, 1829. At the outbreak of the Civil War she went to the front with the regiment of which her husband was colonel, and served throughout the war at the head of a company of Red Cross nurses. She leaves no children. Her entire fortune, amounting to about $1,250,000, is bequeathed to the Loomis Institute, of Windsor, Conn., for the foundation of a technological school.

TWO CENTENARIANS. — Mrs. Mary Boss, who died last week at Schenectady, N. Y., was locally reputed to be one hundred and four years of age. She was born in Germany.

William Macabee, who died last week at Philadelphia, is said to have been born in Baltimore on Sept. 22, 1803. At the time of his death he was the oldest veteran of the Civil War, and he was the last survivor of the crew of the frigate *Constitution*, on which he enlisted shortly after the War of 1812, and on which he served for many years. He fought as an able-bodied seaman throughout the Civil War, and continued in the navy afterwards until age compelled his retirement.

OFFICERS OF THE ROENTGEN RAY SOCIETY. — At the annual meeting of the American Roentgen Ray Society, recently held at Detroit, Dr. Percy Brown, of Boston, was elected president of the society for the ensuing year; Dr. Walter C. Hill, of Cleveland, Dr. Willis Manges, of Philadelphia, and Dr. A. C. Skinner, of Kansas City, were elected vice-presidents; Dr. F. H. Baetzer, of Baltimore, secretary; and Dr. Charles F. Bowen, of Columbus, treasurer. Dr. Fedor Haenisch, of Hamburg, the delegate of the German Roentgen Association to the meeting, is in Boston this week on his way to return to Germany.

THE HARVEY SOCIETY. — The lecture course of 1910–11 under the patronage of the New York Academy of Medicine is as follows: Oct. 15, 1910, Prof. H. Chiari, University of Strassburg, "Die Bedeutung der pathologischen Autopsie und sonstiger pathologisch-anatomischer Untersuchungen." Nov. 5, Prof. W. E. Castle, Harvard University, "Unit Characters in Heredity." Nov. 19, Prof. Jacques Loeb, Rockefeller Institute for Medical Research, "The Prevention of the Toxic Action of Various Agencies through the Prevention of Oxidation in the Cell." Dec. 10, Prof. Harvey Cushing, Johns Hopkins University, "Certain Clinical Aspects of Dyspituitarism." Jan. 14, 1911, Prof. Arthur R. Cushny, University of London, "Therapeutics of Digitalis." Feb. 4, Dr. Thomas B. Osborne, Connecticut State Agricultural Experiment Station, "The Chemistry of the Proteins." March 25, Prof. H. Gideon Wells, University of Chicago, "Calcification and Ossification."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Oct. 11, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 22, typhoid fever 33, measles 9, smallpox 0, tuberculosis 61.

The death-rate of the reported deaths for the week ending Oct. 11, 1910, was 16.33.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 8, 1910,

was 220, against 201 the corresponding week of last year, showing an increase of 19 deaths, and making the death-rate for the week, 17.11. Of this number 100 were males and 120 were females; 216 were white and 4 colored; 143 were born in the United States, 74 in foreign countries and 3 unknown; 43 were of American parentage, 156 of foreign parentage and 21 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 32 cases and 6 deaths; scarlatina, 29 cases and 1 death; typhoid fever, 32 cases and 3 deaths; measles, 10 cases and 0 deaths; tuberculosis, 61 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 20, whooping cough 2, heart disease 28, bronchitis 0. There were 12 deaths from violent causes. The number of children who died under one year was 52; the number under five years, 72. The number of persons who died over sixty years of age was 52. The deaths in public institutions were 77. Cerebrospinal meningitis, 4 cases and 1 death. Anterior poliomyelitis, 3 cases and 3 deaths.

Of the above infectious diseases the following were non-residents: Consumption, 2 cases. Diphtheria, 1 case. Typhoid fever, 7 cases and 1 death. Scarlet fever, 2 cases.

Deducting deaths of non-residents, the total is 200 and the death-rate is then 15.55.

Bequest to the Dorchester Home for Consumptives. — Among other charitable bequests in the will of the late Margaret Horrigan, of Cambridge, Mass., which was filed last week in the Middlesex Probate Court, is one of $200 to the Free Home for Consumptives, Dorchester.

Sale of Impure Vinegar. — In the Boston municipal court last week, a corporation engaged in the manufacture and sale of vinegar in this city was fined $100 "for having in its possession on July 18 last, with intent to sell, and for selling on Sept. 23, vinegar containing caramel coloring matter," in violation of the regulations of the Board of Health.

Poliomyelitis in Rhode Island. — The epidemic of poliomyelitis in Rhode Island continues. On Oct. 7, three new cases of acute poliomyelitis were reported to the Rhode Island State Board of Health, one in Providence, one in Cumberland, and one in Anthony. In Providence there was also one death from the disease on the same day. This makes a total of 166 cases reported in Rhode Island since June 1, and 194 cases with 22 deaths since the beginning of the current year.

Endowment Needed for a Tuberculosis Camp. — Two years ago Mrs. Theodore K. Gibbs purchased for $20,000 a tract of land in Middletown, R. I., and offered to erect on it and present to the Newport (R. I.) Hospital a tuberculosis camp. This offer the hospital refused until adequate endowment for the camp should be provided. That endowment is not yet forthcoming and the enterprise still awaits the generosity of some philanthropist for its completion.

Work of the Boston Floating Hospital. — The Board of Trustees of the Boston Floating Hospital publishes the following statement of the work done by the hospital during the season of 1909. "Last summer 384 different permanent patients received care for an average of 19 days of twenty-four hours each, or a total of 7,367 full days' service; 667 day patients made 4,683 day trips; mothers who accompanied their sick children and received instruction in nursing, helping in their care, made 4,874 day trips; 831 day trips were made by well children too small to be left at home by their mothers. This represents a service to the beneficiaries of this work of a total of 17,755 days for the summer of 1909." This record gives strong enforcement to the appeal made by the trustees for donations to meet the expenses of the season just ended and make possible the continuance and extension next year of this valuable medical charity.

"Ether Day" at the Massachusetts General Hospital. — In our issue of last week we announced that "Ether Day" at the Massachusetts General Hospital on Oct. 15 would be addressed by Dr. Geo. W. Crile, of Cleveland, Ohio. This fact in itself should lead to a large attendance on the part of the medical profession in this vicinity. It may not be generally known, but for some years past the meeting commemorative of the discovery and practical use of ether at the Massachusetts General Hospital has assumed a somewhat formal character, with an address from a man distinguished in some walk of life, though not necessarily in medicine. This year the address is to be made by a surgeon of originality who has done much to forward the science of medicine in his line, and it is not to be doubted that his address will be of vital interest, particularly to the medical profession. It is to be hoped the attendance will be generous.

Physical Examination of City Laborers. — The Civil Service Commission has recently adopted a regulation providing for compulsory physical examination of all applicants for employment as laborers by the city of Boston. This regulation, which becomes operative on and after Dec. 5, 1910, requires examination by a physical inspector as part of the test for general fitness of every candidate. The physical defects enumerated as deemed sufficient cause to warrant rejection are: Serious defects of sight or hearing, cardiac or pulmonary disease, paralysis, serious spinal deformities, stiff joints, loss of limb such as to impair present or future usefulness, marked flat foot, severe varicose veins or ulcers. In addition every man will be required to pass a strength test by demonstrating his ability to lift, shoulder and carry a 'sack containing 75 pounds' weight. It is surprising to find that such a regulation has not previously been in existence. Its adoption now should not only increase the physical efficiency of the city's labor force, but should to a certain extent lessen the opportunity for graft in the employment of those incapable of rendering the service for which they are paid.

NEW YORK.

Open-Air School at Montclair, N. J. — On Oct. 3 it is proposed to inaugurate an open-air public school for children not of good health in Montclair, N. J. A tent will be used for the purposes of the school, with arrangements for a maximum of fresh air. A wooden floor will be provided and regulation school desks. The clothing to be worn is to consist of woolen garments and a bag made of warm material which may be drawn over the feet in cold weather. Heated soapstone is to be used to keep the feet of the children warm. No decision has yet been reached regarding the food, and until this question is decided there will be only one session of the school daily.

The Lobster and Typhoid Fever. — While the lobster has been accused of giving rise to many "ills," it has not hitherto been regarded, like the oyster, as a source of typhoid fever. This charge has now been brought against it in the case of a number of persons who partook of a dinner given on Sept. 7 under the auspices of a certain political and social club of Elizabeth, N. J., at which lobster salad was a prominent feature. It is, of course, quite possible that the typhoid infection may have been contracted from some other ingredient of the salad, or from some other viand than the salad, but it is an unquestionable fact that a considerable number of those at this dinner have been attacked with the disease. On Sept. 27, there were sixteen serious cases, and three others had already proved fatal, while the bacteriological tests have shown that the affection is genuine typhoid fever. In the meanwhile Health Officer Richards has secured the names of all who attended the dinner and of all dealers who furnished the food served at it, and has commenced an investigation which it is to be hoped will definitely settle the source of infection.

International Pure Milk League. — "The International Pure Milk League" has been incorporated in the county of New York by a number of prominent women. The objects of the league are stated to be, "to foster and encourage the production, distribution and consumption of pure milk and pure food generally; to foster and promote the common interests of producers, dealers and consumers of milk and all other articles of food; to foster and promote methods of cleanliness in the handling of milk and all other articles of food, from the producer to the consumer, throughout the civilized world; to foster and promote local and foreign organizations of a similar purpose, with or without the league as a central or parent body."

"A Budget Show." — A "Budget Show," a novelty in municipal undertakings, in which all the various departments of the city's administration have exhibits, was opened in a commodious building on Broadway on Oct. 3. Mayor Gaynor, who appeared at the City Hall on that day for the first time since his attempted assassination, was expected to have charge of the opening ceremonies, but as it was deemed inadvisable for him in his present state of health, President Mitchell, of the Board of Aldermen, officiated in his place. The work of the Health Department in combating disease and promoting sanitation is admirably represented in this exhibition, and on Oct. 4 Commissioner Lederle made an address in which he set forth the special needs of the department. In the Division of Child Hygiene an increase of $316,145 for next year is asked for, and this includes provision for the employment of 266 nurses in addition to the present force of 142, and 49 medical inspectors in addition to the present number, 161, in order to admit of the physical examination of the children attending all the free schools of the city, instead of, as at present, the public schools only, and to continue throughout the year the instruction of mothers in the care of

their infants, instead of, as at present, during the summer months only. The largest increase, $487,796, is asked for the Division of Hospitals in order to provide one physician to every forty patients, one day nurse to every ten patients and one night nurse to every fifteen patients. The present appropriation makes allowance for only one physician to every ninety patients, one day nurse to every sixteen patients, and one night nurse to every twenty-one patients.

SPECIAL ARTICLE.

Epidemic Poliomyelitis. A Discussion of the Prevalent Infantile Paralysis.

11. Levison and Dachtler conclude their article as follows: Roentgen examination affords an unexcelled method of controlling the results obtained by physical diagnosis. The teleoroentgenographic method reduces the error by distortion to a negligible quantity and is well adapted to routine work. The anatomic location of the normal thymus renders its differentiation by Roentgen rays improbable. The demarcation of heart borders in terms of bony landmarks does not offer a fair comparison with adults, owing to the continued change in the development of the bony structures. Absolute heart-dullness in children can be quite accurately determined by very light percussion and the results confirmed by Roentgen rays. The relatively great volume of the great thoracic vessels in children offers the greatest difficulty in determining the size of the heart by physical methods only. Extremely light percussion has not given us normal impaired resonance between the upper borders of the great vessels and the clavicle. Roentgen examination has confirmed the absence of a density of tissue which would produce such dullness.

14. Meltzer's excellent article gives a very clear idea of the process of anaphylaxis and is summed up as follows: It is generally agreed that the so-called nervous asthma is due to a stenosis of the bronchioli. It was discovered that the so-called anaphylactic shock is due also to a stenosis of the fine bronchi. The theory is here offered that asthma is an anaphylactic phenomenon, that is, that asthmatics are individuals who are "sensitised" to a specific substance, and the attack of asthma sets in whenever they are "intoxicated" by that substance. It has been proven that the anaphylactic attack is of peripheral and not of central origin. It is, therefore, suggested that the so-called nervous asthma is also due to a peripheral and not a central cause. In other words, "nervous asthma" is not a neurosis.

13. *MURPHY, J. B. *The Arsenical Treatment of Syphilis.*

8. Walter, from his bacteriologic investigations, concludes that the diphtheroids, particularly the Bacillus Segmentosus, are concerned in the production of the so-called common cold in its typical manifestation in the nose, and there is much evidence that it occurs in epidemic form. The micrococcus catarrhalis is much more common in its manifestation and is probably also epidemic and productive of more severe inflammation, though mild epidemics occur. It seems likely that a mixed infection of these two types increases the virulence. The pneumobacillus of Friedländer is much more concerned in chronic conditions and is probably identical with the ozena bacillus. The pneumococcus of Fränkel flourishes in any part of the upper respiratory tract. Segmentosus is most likely to be in the nose, seldom in the trachea, and may cause otitis media. Catarrhalis is most apt of all to invade the larynx and trachea. The pneumobacillus is mostly confined to the nose and sinuses. Influenza bacilli are conspicuous by their absence. Pyogenic cocci are nonpathogenic locally, except as secondary invaders.

10. Saenger presents an historical review of the theories of choked disk and advances his own that the main cause is increased cerebral tension. This is substantiated by the rapid disappearance of the condition after decompression in cerebral tumors. He advises decompression at the beginning of visual diminution, before atrophy of the optic nerve develops.

12. Flexner gives a complete review of our present-day knowledge of anterior poliomyelitis, with special reference to recent experimental results. It is a very comprehensive paper.

13. Murphy advises the use of the sodium cacodylate of arsenic in the treatment of all stages of syphilis. It is given in 3 to 6 gr. doses by mouth or 1 to 2 gr. doses daily hypodermically. It is remarkable how quickly the spirochete will disappear from mucous patches or the primary sore under this treatment. This is the safest arsenical preparation to use, and seems to be a specific against the spirochete. [E. H. R.]

12. WEAVER, G. H. *The Effects of Injections of Killed Streptococci.*

1. Henderson describes the actions of digitalis upon the heart as (1) stimulation of the cardio-inhibitory center decreasing rhythmicity; (2) increase in the power of contractility; (3) increase in tonicity; and (4) depression of conductivity. These effects may be exerted more promptly than by the mouth administration of digitalis by the intravenous use of strophanthin. Cases are reported where strophanthin injections were given and systolic and diastolic blood-pressures were followed to determine the work of the heart by Von Recklinghausen's method, but the clinical improvement showed more striking evidence of the effect than the figures supposed to represent heart work. Henderson believes that the intravenous use of strophanthin is of value in giving prompt benefit where any favorable results are to be obtained from the digitalis group of drugs, and that where it fails recourse must at once be had to other lines of treatment.

2. Friedenwald reports 14 cases of digestive gastric hypersecretion as distinguished from continuous gastric hypersecretion. The condition is defined as one where abnormally large amounts of gastric secretion are obtained after a test meal, although the fasting stomach contains but a few cubic centimeters of juice. The great majority of cases occur in men. The symptoms are largely those of gastric neurasthenia, with sense of fullness, eructations and pains, with occasionally nausea and vomiting, rarely heartburn, and usually extreme constipation. Appetite remains good, but marked loss of weight is present in all instances. Succussion is present even after small meals. The amount of stomach contents obtained after a test meal is always large, separating into two layers, — a deep layer of almost clear fluid with below it a comparatively small stratum of solid sediment. Even after a dry test breakfast, large amounts of fluid are withdrawn, but from the fasting stomach little or nothing can be extracted. The condition may be transient or may pass over into continuous hypersecretion. It is undoubtedly of nervous origin, and in treatment attention is to be directed largely to improving the general health and building up the nervous system by rest, hydrotherapy and massage.

3. Sailer reviews the development of our knowledge of pancreatic disease and its present status. Chronic pancreatitis consists of degenerative changes in cells, proliferation of connective tissue and round-cell infiltration, and is accompanied by insufficiency of pancreatic secretion. Clinically cases fall into three classes. (1) Cases with jaundice, distended gall bladder, emaciation, digestive disturbance and changes in secretions and discharges, sometimes with palpable tumor in the region of the umbilicus. (2) Cases where swelling of the head of the pancreas is the chief clinical feature. (3) Cases where the diagnosis cannot be established clinically, but where pancreatitis is suspected either by the surgeon, who detects unusual hardness at operation, or by the physician as a result of symptoms, signs and laboratory tests. The chief symptoms are malnutrition, disturbed digestion with discomfort or actual pain. Numerous tests of pancreatic function have been employed, but their diagnostic value remains unestablished. In treatment benefit has been reported after various surgical procedures, but medical treatment is not to be neglected. This comprises, in addition to general attention to digestion and nutrition, the use of pancreatic extract in glutoid capsules.

5. McDonald calls attention to the lack of accuracy of the prevailing methods of estimating the duration of pregnancy, and proposes a new method for its determination. The duration of pregnancy in lunar months is found to equal the height of the uterus in centimeters divided by 3.5. After the sixth month this rule has been found to be very exact.

8. Orbison refers to the description by Spiller and by Oppenheim of cases which have been diagnosticated either as epilepsy or as hysteria, but do not properly belong to either disease, being simply manifestations of psychasthenia without relation to hysteria or to epilepsy. It is to be recognized that in certain cases of psychasthenia convulsive attacks may occur which are not of grave prognosis.

11. James and Williams describe the string galvanometer and the electrocardiogram in health. The electrocardiogram is a graphic record of electric currents set up by the heart beat as shown by the apparatus of Einthoven. Certain waves are observed with each beat of the heart, the chief one being definitely associated with the contraction of the ventricle. A smaller wave probably results from the contraction of the auricle, and other events occur the significance of which is not yet established, but which serve to give the electrocardiogram of the normal case a characteristic form. [F. W. P.]

3. *SCHWYZER, A. *Transgastric Jejunal Feeding.*
4. *SUTTON, W. S. *The Proposed Fistulo-Enterostomy of Von Stubenrauch.*
5. LILIENTHAL, H. *Permanent Colostomy.*
6. MATHEWS, F. S. *Myeloma of the Long Bones.*

1. Hunt and Woolsey present a very careful study of thirteen cases of spinal cord tumors, of which 6 were extramedullary. Hunt, after a survey of symptoms and signs for localization, gives the thirteen case histories. These are given first in summary, then in detail, and are finally discussed from point of view of diagnosis, symptomatology and localization. They are highly instructive and forcibly impress the significance of the introductory survey. Woolsey then gives the operative technic, the mortality, the after-treatment and the results, immediate and ultimate. Any group of symptoms indicating a progressive focal lesion of the cord is considered suggestive of the possibility of neoplasm. Much attention is given to the differentiation of extra- and intra-medullary tumors. An absolute diagnosis is not always possible owing to exceptions which occur in the symptomatology of either variety. When in doubt, both authors agree that the patient should always receive the benefit of the doubt and be subjected to exploratory laminectomy without undue delay. Spinal cord tumors generally begin with localized pain due to involvement of meninges or more especially the posterior roots, followed after a valuable period by symptoms of gradual impression of the cord (sensory, motor and sphincter disturbances). With some exceptions vertebral and extradural tumors present bilateral root and medullary symptoms, while intradural tumors present unilateral symptoms. Although a zone of hyperesthesia corresponding to the upper level of compression is far from constant, it is a valuable localizing sign, when present. Rigidity of the spine with localized pain and tenderness, so characteristic of vertebral tumors, may also accompany intravertebral growths. The root pains are segmental in distribution and do not, as in true neuralgia, follow the course of nerve trunks, and are of great value in determining the level of the lesion indicating compression of the segment from which the root springs and not of the root in its intraspinal course. In intramedullary tumors root-pains are often absent or insignificant. Loss of pain and temperature sense (dissociated anesthesia) may be en-

countered in vertebral and extramedullary lesions as well as in central lesions. Atrophic palsies occur in both central and eccentric growths, but atrophy dependent upon extensive longitudinal involvement of the cord accompanied by fibrillary twitchings, especially associated with loss of pain and temperature sense, homolateral and of segmental distribution, is very characteristic of central tumors. In extramedullary tumors of the cervical region Hunt has often observed a distinct girdle sensation at the umbilical or lower thoracic level. Woolsey favors a simple laminectomy, if possible in a modified left Sims' position, always with the part of the spine in question higher than the head and rest of the spine to limit the escape of cerebrospinal fluid when the dura is opened. Urotropin is given before and after operation until wound is healed or until catheterization is no longer necessary. By sight in many cases it is difficult to determine whether the tumor is extra- or intra-medullary owing to the lamellated, edematous condition of the arachnoid over the tumor. This must be incised. At least three successive nerve roots must be divided to produce cutaneous anesthesia. Simple section without suture is practised and advised in all cases of inoperable tumor to relieve pain. The authors' mortality (7 cases) was 14.3%, but, including 2 exploratory operations and 1 case of endothelioma of upper sacral vertebræ, the mortality was only 10%.

2. Stone reports 4 cases of intestinal lesions from blunt force, 3 with rupture and 1 with contusion and bowel paralysis. All were operated immediately upon admission to the University of Virginia Hospital, admission occurring thirty-six to one hundred and one hours after accident. In all cases the small intestine sustained injury. The case of adynamic ileus was in a boy who had been jammed against a gate-post by a charging cow. There was immediate sharp abdominal pain and vomiting. The vomiting soon ceased and did not recur. Belly showed distention without rigidity or marked tenderness, no peristalsis and no free fluid. There was no leucocytosis. Operation showed 14 cm. of contused gut with distended gut above and collapsed gut below. Enterostomy. No drainage. Second operation with mechanical emptying of the bowel after direct application of eserin failed. Third operation, closure of fistula. Recovery. Stone advises exploratory laparotomy in all cases of abdominal blunt injury.

3. Schwyzer reports a case upon which he did a gastrojejunostomy with a Murphy button and then a small gastrostomy. A catheter was passed through the gastrostomy opening *via* the button into the distal loop of jejunum. Through this tube the desperately ill patient was fed. Vomitus or stomach contents from washings were found to be best tolerated and had the advantage of containing some digestive secretions.

4. Sutton reports a case of persistent biliary fistula upon which was performed the fistulo-enterostomy proposed by Von Stubenrauch, "the first application of this method to the human subject." The operation was found to be feasible, but a failure on physiologic grounds. [T. W. H.]

12. Hird, A. E. W. *A Case of Cerebellar Hemorrhage.*

2. McDonagh briefly reports his results with the use of Ehrlich's new preparation for the treatment of syphilis. This drug aims to kill definitely this infecting organism. Over-sensitiveness to arsenic should be tested for, prior to the use of the drug, by a conjunctival test. He describes the technic of injection either intramuscularly or intravenously. In addition to remarkable changes for the better in the condition of the local lesion, he records a great improvement in the patient's general condition.

3. McIntosh reports his experiments with the new Ehrlich preparation "606" on recurrent fever in rats. He concludes from his researches that this is a specific remedy for European relapsing fever.

4. Tod urges ossiculectomy instead of a radical mastoid operation in chronic middle-ear suppuration for the following reasons: (1) A large number of cases can be cured or a radical mastoid operation avoided by this comparatively simple procedure. (2) The large proportion in which a good result is obtained in regard to hearing power by this method. (3) There is slight inconvenience to the patient and only a short period of after-treatment.

10. The writers' have isolated from the feces, heart, blood, etc., of cases dying of epidemic diarrhea two distinct groups of organisms producing diarrhea in puppies. These groups are distinguishable from each other and from the Paratyphoid B. They were not present in the stools of one hundred normal children. [J. B. H.]

16. MACKENZIE, H. *Care of the Mouth during General Disorders.*
17. UNDERWOOD, A. S. *The Influence of Climate on Dental Caries.*

1. Bryce comments on osteopathy as he has studied it in England and America. He explains the cause of the benefit often obtained, and urges surgeons to employ some of the rigorous manipulative methods advocated by osteopaths. On the other hand, he deplores the harm that is often done and exposes the absurdity of the osteopath, who attempts to explain all diseases by subluxation and displacements.

6. Milne does not believe in isolating scarlet fever patients. Commencing at the earliest possible moment during the first four days he rubs the child all over, head to foot, with pure eucalyptus oil night and morning; afterwards this is repeated once a day until the tenth day. For twenty-four hours he swabs out the tonsils with 1:10 carbolic oil every two hours. He claims that by this method secondary infections are unknown, that isolation is unnecessary, and that this method is vastly more economical. [J. B. H.]

4. Fleischer and Takeda have taken up and studied the test for the detection of levulose in the urine as suggested by Pinoff in 1905. They tried it out on a number of cases and concluded that it was a sharper reaction than the Seliwanoff reaction, but not absolutely reliable, as the result was positive in certain cases where there was no levulose. They hope eventually to find what other substances besides levulose will give the reaction.

8. Tornai warns against the use of the Momburg constriction belt in any except the most suitable cases as he has seen poor results in cases that show any lesion of the heart or kidney. Also in Basedow's disease and plethoric individuals he does not think this method should be used as death may result. [C. F., JR.]

8. The author has found that he has obtained much better results both in the abortive treatment of gonorrhea and in the treatment of chronic cases by using protargol 0.5% to 3% at a temperature of about 115° F. than by the use of the same injections at normal temperature. He gives his reasons and describes his technic. He lays emphasis on the fact that the protargol must be freshly prepared as it degenerates very rapidly. [J. L. H.]

Miscellany.

EHRLICH'S NEW PREPARATION (606) IN THE TREATMENT OF SYPHILIS.

DR. HENRY W. CATTELL recently spoke before the Philadelphia County Medical Society on the technic used in Wechselmann's wards of the Virchow Hospital in Berlin for the treatment of syphilis with Ehrlich's Preparation "606" and said: I saw towards the end of July five injections given with "606," and had the opportunity of examining about 100 cases in all so treated.

Our knowledge in regard to syphilis has been increased by:

(1) The discovery of the active agent by Schaudinn and Hoffmann.

(2) The diagnosis of the poison by means of the Wassermann reaction or one of its various modifications.

(3) The inoculation of apes, rabbits and guinea-pigs with syphilis.

The capsule containing the yellowish compound, diamidade-oxyarsenobenzene, is broken and collected in a sterile mortar and dissolved in 1 to 2 ccm. of *concentrated* sodium hydrate. Methyl alcohol is no longer employed. After solution has taken place the preparation is again precipitated by the addition of *glacial* acetic acid. Fifteen to 20 ccm. of sterile water are added, and the whole centrifugated, the supernatant water poured off, more water added, and the whole

brought to neutral by either the addition of a decinormal solution of sodium hydrate or of a 1% solution of acetic acid. The dose used at the time I was in Berlin was 0.5 to 0.6 gm. for an adult and 0.025 gm. for a babe. The preparation is injected in a large syringe beneath the scapula in an area which has first been painted with iodine. One of the strong reasons for choosing the subscapular region is that, in case of arsenicalism, the location is easy of access surgically. A lump is formed which requires some time to disappear. The injections are sometimes followed by pain, fever or malaise, immediately afterwards or coming on after several days. The oldest case of inoculation is now between eleven and twelve months, and Ehrlich must have now nearly 8,000 records, 7 deaths, of treated cases. It is perfectly marvelous to see a patient come into the wards with pronounced evidences of the disease, and to observe the immediate improvement after treatment. The spirochetes begin to disappear the first day, and in forty-eight to seventy-two hours they are no longer to be found. The Wassermann may, however, remain positive for several weeks.

A test similar to that employed in the Calmette or Von Pirquet reaction must always be made to determine whether or not the patient has been treated before by arsenic or is peculiarly susceptible to the drug. Ehrlich insists that everybody before being inoculated should have the eyes examined and to see that there are no complications like grave heart or kidney disease present. This mode of treatment has been done by the best observers that Europe affords, and has been undertaken under control conditions, such as have never existed before. The results so far have been perfectly astonishing, though I saw three cases in Wechselmann's hands which had returned for a second treatment. The reason given for this was that these were some of the earlier cases in which too small a dose had been administered.

The users of this remedy are so enthusiastic that they advise it in practically every case. In one of the wards there were no less than ten syphilitic babies suffering from every manifestation of inherited syphilis.

Correspondence.

CLEAN SWEET MILK AND "VOTES FOR WOMEN."

BOSTON, Oct. 1, 1910.

Mr. Editor: Some days ago I received, as doubtless did many other Massachusetts doctors, a number of highly illuminated cards advocating "clean, sweet milk" and "votes for women." At first thought these two principles seemed to have about as much in common with each other as either would with protection or free trade. But further consideration suggests that there may be a connection, after all, between healthful milk for babes and woman's vote, inasmuch as the domestic woman is rather more likely than her ballot-seeking sister to provide the best food for babies from her own fountains. I have indeed been led to question whether the best product of the lacteal glands was secured when they covered the beating heart of a militant suffragette.

So I replied briefly, in the self-addressed envelope that accompanied the literature, that I did greatly favor clean, sweet milk but *not* votes for women. I have just received the enclosed reply, which for clear, cogent reasoning and delightful English would be hard to equal:

"DR. —

"*Dear Sir:* For your semi-indorsement of my efforts in behalf of Hygiene Milk I am grateful. Please do not do it again, I will forgive you this time.

"Sir, I am really shocked at your inconsistent inference that it would be possible for a woman, backed with the authority of the United States federal government to supervise the production and protection of milk, to contaminate it to any higher degree of efficiency to kill than is done to-day by a man. Its very, very high degree of efficiency to kill is attested by the Boston Health Board's report that fifty-one babies in the city of Boston died during the month of July, 1910, in access of the number in July, 1909.

"Sir, no acknowledgment or reply is required to this note until the scales have been removed from your callous conscience, by the torture and the filling of a permature grave of a dear one to you.

"In consequence of a diet upon a concentrated stewed solution of dirt, tubicolous and bacterial germs.

"Doctor, you may be skillful and in the full possession of the knowledge of medical science.

"Kindly accept the following from a layman, that combined brand of the dairy and milkman's indifference known as the undertakers' delight, that has been supervised by a man often, from the viewpoint of the quality and courtesy of the dairyman's whiskey and cigars is a master piece of production warrented to kill, when taken as a food and is far, far from the scope of known medical science to combat.

"Doctor, pull yourself together, this world moves. Respectfully, ———, Champion of Clean, Sweet Milk, Its production and protection supervised by a woman, backed by the authority of my uncle Samuel of Washington, District of Columbia, United States of America."

Yours truly,

"X."

"THE PATIENT TO THE DOCTOR."

BOSTON, Oct. 3, 1910.

Mr. Editor: For fear you might not otherwise see it, I cannot refrain from sending you this bit of verse, from a recent number of the *Century*, which seems to me thoroughly charming. Its author, Harold Witter Bynner, who has a peculiarly winning and graceful talent, is perhaps best known for his "Ode to Harvard." Since William E. Henley's "Hospital Verses," little medical verse of genuine poetic value has been written. These lines of Mr. Bynner's, though perhaps hardly in the same category, have a very sweet human touch to which the profession should not be insensible. If you feel disposed to reprint them, I hope they may give your readers as much pleasure as they have me.

Very truly yours,

ROBERT M. GREEN, M.D.

THE PATIENT TO THE DOCTOR.

[Witter Bynner in the *Century*.]

Name me no names for my disease
With uninforming breath;
I tell you I am none of these,
But homesick unto death, —

Homesick for hills that I had known,
For brooks that I had crossed,
Before I met this flesh and bone
And followed and was lost.

Perhaps it broke my heart at last,
But name no name of ills;
Say only, "Here is where he passed,
Seeking again those hills."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCT. 1, 1910.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED SEPT. 28, 1910.

WILLIAMS, L. L., surgeon. Leave of absence for seven days from Sept. 19, 1910, amended to read three days from Sept. 19, 1910, under paragraph 189, Service Regulations.

GARDNER, C. H., surgeon. Leave of absence for one month from Sept. 1, 1910, amended to read twenty-two days from Sept. 1, 1910.

SPRAGUE, E. K., surgeon. Granted one month's leave of absence from Sept. 28, 1910.

RUCKER, W. C., passed assistant surgeon. Relieved from duty in connection with the suppression of plague in California, and detailed for temporary duty in the Bureau, effective Sept. 22, 1910. Sept. 23, 1910.

CREEL, R. H., passed assistant surgeon. Detached from U. S. R. C. "Tahoma" and ordered on shore duty at Unalaska, as fleet surgeon. Aug. 9, 1910.

GUTHRIE, M. C., passed assistant surgeon. Granted one month's leave of absence from Oct. 1, 1910.

HUNT, REID, professor, chief division of pharmacology, Hygienic Laboratory. Detailed to attend the Second International Conference for the Study of Cancer, to be held in Paris, Oct. 1-5, 1910, and the Conference of the International Anti-Tuberculosis Association, to be held in Brussels, Oct. 5-8, 1910. Sept. 22, 1910.

PORTER, JOSEPH Y., quarantine inspector. Granted thirty days' leave of absence from Sept. 20, 1910.

BARNES, W., acting assistant surgeon. Granted thirty days' leave of absence from Oct. 5, 1910, with pay, and one month's leave of absence from Nov. 5, 1910, without pay.

CLARK, E. S., acting assistant surgeon. Granted thirty days' leave of absence from Sept. 13, 1910.

CLERBORNE, A. B., acting assistant surgeon. Granted seven days' leave of absence from Sept. 24, 1910, under paragraph 210, Service Regulations.

GILL, S. G., acting assistant surgeon. Granted one day's leave of absence, Sept. 17, 1910, under paragraph 210, Service Regulations.

KIMMET, W. A., acting assistant surgeon. Granted thirty days' leave of absence from Sept. 25, 1910.

RUSH, JOHN O., acting assistant surgeon. Granted ten days' leave of absence from Sept. 24, 1910, without pay.

SCHUSTER, B. L., acting assistant surgeon. Granted one day's leave of absence, Sept. 10, 1910.

STUART, A. F., acting assistant surgeon. Granted thirty days' leave of absence from Oct. 1, 1910.

WAKEFIELD, H. C., acting assistant surgeon. Granted fourteen days' leave of absence from Oct. 10, 1910.

SCOTT, E. B., pharmacist. Granted five days' leave of absence from Sept. 15, 1910, under paragraph 210, Service Regulations.

RYDER, L. W., pharmacist. Granted four days' from Aug. 24, and thirteen days' from Sept. 1, 1910, extension of leave of absence on account of sickness. Granted seven days' leave of absence from Sept. 14, 1910, under paragraph 210, Service Regulations.

PHYSIOLOGICAL SEMINAR.

PROF. W. T. PORTER will give a physiological demonstration and an informal lecture every Monday and Thursday afternoon in the Harvard Medical School, room 302, Building C, from five to six o'clock.

ERRATUM.

ATTENTION has been called to the fact that in the index of this JOURNAL, vol. clxii, the page number referring to the article "Infantile Paralysis, Methods of Treatment" is incorrect. The number of the page should be 881.

SOCIETY NOTICES.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — The New England Hospital Medical Society will hold its regular meeting Thursday, Oct. 20, at the Kensington Chambers, Room 201, corner Boylston and Exeter streets, Boston. Dr. Agnes C. Vietor, chairman. Subject: Gall-Bladder Disease. Papers: (1) "The Pathology of the Gall Bladder," (2) "The Diagnosis of Gall Bladder." By Agnes C. Vietor, M.D. (3) "The Surgical Treatment of Gall Bladder." By James G. Mumford, M.D.

DR. BLANCHE A. DENIG,
Secretary.

NEW YORK AND NEW ENGLAND ASSOCIATION RAILWAY SURGEONS. — The twentieth annual session of the New York and New England Association Railway Surgeons will be held at the Hotel Astor, Broadway and 44th Street, New York City, on Nov. 3-4, 1910, under the presidency of Dr. L. M. Bingham, of Burlington, Vt. Dr. John B. Deaver, of Philadelphia, will deliver the "Address on Surgery," on Nov. 3, at 12 o'clock. A cordial invitation is extended to railway officials, railway surgeons and to the medical profession to attend this session of the association.

GEO. CHAFFEE,
Corresponding Secretary.

RECENT DEATHS.

DR. J. MILLER HINSON, of Brookline, Mass., who died at Saratoga, N. Y., on Oct. 4, was a graduate of the Hahnemann Medical College of Philadelphia. He is survived by his widow and by one son.

DR. CORNELIUS GILMAN TROW, who died last week at Sunderland, Mass., was born in Buckland, Mass., in 1847, the son of a physician. He graduated from Amherst College in 1870 and subsequently studied medicine at the New York College of Physicians and Surgeons. In 1872 he settled with his father at Sunderland, where he continued in practise till his death. He served for many years as chairman of the local school committee and as trustee of the public library. He was a Fellow of The Massachusetts Medical Society. Dr. Trow was twice married, but leaves no children. His widow survives him.

DR. RUDOLF CHROBAK, who has recently died at Vienna, was born at Troppau, in Silesia, on July 8, 1843. He received his doctorate of medicine from the University of Vienna in 1865, and in 1880 was made Professor of Obstetrics and Gynecology. Since 1889 he has been at the head of the Second Obstetrical Clinic in Vienna. He was a prolific writer on subjects in the field of his specialty.

Original Articles.

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES F. PAINTER, M.D., AND ANDREW P. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

For many years the surgical profession have been loath to interfere with pathologic or traumatic conditions located within the larger articulations.

The reasons for this have been the dangers of sepsis and the fear that permanent damage might be done to an articulation by the extent of the incision.

With the development of greater perfection in surgical technic the first of these fears has been, to a certain extent, eliminated. The fear of inflicting permanent injury upon a joint through the weakening of its capsule is still a deterring factor in the minds of many surgeons. The fact that sepsis has occurred in a certain small percentage of cases, perhaps not more frequently, however, than it occurs in other surgical wounds, and the fact that many of the conditions for which an arthrotomy might be and usually is performed are those which do not permanently endanger life or limb, there have been good grounds for the exercise of conservatism in the matter of arthrotomy. It certainly should be considered seriously, when contemplating a major operation upon a joint, whether the object which it is sought to accomplish by the procedure justifies the assumption of a risk which no one would hesitate to assume were the condition which one was seeking to relieve a mortal one, but might hesitate about when not of such gravity. The general surgeon has doubtless been justified in his conservatism about the operative treatment of joint lesions. Many of them, however, though they do not menace life directly, do seriously handicap, either temporarily or permanently, the individual who possesses them from attaining his highest efficiency as well as preventing him from enjoying the free use of his joints.

It, therefore, seems that if surgical technic as it has become perfected can attain the results that it sets out to accomplish in the treatment of joints, and if the skill with which such procedures can be carried out has reached a sufficient degree of perfection to minimize the risks over what they have been during the past ten years, it is justifiable now to undertake surgical procedures which formerly would not have been justified.

It is for the purpose of demonstrating the risks which attend arthrotomies on the large joints, and to describe methods which have yielded measurably satisfactory results, and to outline the conditions in which arthrotomy offers its most favorable prospects of success that the statistics which are contained in this paper have been compiled. The paper will be incomplete, in that it will not touch many things which fall to the lot of one who is dealing with joint surgery. Except for the pathological conditions which will be brought to light in the class of cases which are noted as exceptional in this paper, the methods of attacking the problem, viewed from a surgical standpoint, will be practically the same.

It is also the purpose of this paper to lay stress upon the importance of post-operative treatment in all cases of arthrotomy, because the success of an operation is quite as much dependent upon the skill with which the joint is managed afterwards as it is upon the judgment which determined upon the operation and the skill which carried it to its completion.

The cases have been grouped according to their pathology, and a brief description of the conditions operated upon is all that it seems necessary to give, mainly with a view to investigating the length of time that it was necessary to confine the patient to bed and to the hospital, the rapidity with which normal mobility in the articulations could be secured and the permanancy, where it has been possible to determine it, of the result which was obtained.

These have been the points which we have sought to elucidate in abstracting these histories.

Before each group is outlined the technic of the surgical procedure is described for the particular group of cases which is to succeed. This technic, of course, differs but little for the different pathological conditions which are described.

The first group to be discussed are the joint lipomata, and under this head are included the "solitary lipomata" described by Koenig, the hypertrophied alar ligament fringes which are traumatic fibrolipomata, and the diffuse lipomata which usually represent merely the deposition of fat in the subsynovial tissues as a result of a fatty infiltration, occurring most commonly in persons given to adiposity. The technic of the preparation of these cases and the surgical procedure itself will be next outlined.

JOINT LIPOMATA.[1]

Technic of Operation.

Routine twenty-four-hour preparation of knee. Shave the leg and thigh with a wide margin on both sides of the joint. Scrub with green soap (coarse mitt). Follow this with (*a*) permanganate of potash, (*b*) oxalic acid and (*c*) corrosive (1–3,000). Weak corrosive poultice over the night previous to operation.

Strict aseptic precautions should be exercised in the operating room. Twelve-hour dressing removed from knee, nurse scrubs leg from mid-thigh to mid-calf four minutes with soap and water, Harrington's solution two minutes, corrosive two minutes, after which procedure nothing should come in contact with the knee except that which has been previously sterilized or rendered aseptic. Tourniquet then applied about upper thigh. Depending upon location of tumor, an incision is made about 8 cm. in length, parallel to either outer or inner border of patella. Skin flaps dissected back. Same procedure with

[1] The knee is taken because it is the joint most often concerned.

fascia and adipose tissue, exposing capsule. Latter opened longitudinally and retractors employed to hold cut edges apart. Tumor mass with very thin synovial covering usually protrudes through the capsular opening. Attachment of lipoma then sought out and examined. If very vascular, it should be tied off and then the pedicle may be cut as close as possible to its attachment, thus removing the lipoma from the joint *in toto*. If bleeders are present, they should be tied off with chromic catgut. Joint is inspected and palpated to the satisfaction of the operator. It may be advisable to make a similar incision on the opposite side of the joint for the purpose of a thorough examination. This does not add to the gravity of the case nor interfere with the progress of recovery. The joint cavity should then be irrigated with about two quarts of hot normal salt solution or sterile water. The edges of the capsule are next approximated and sutured with interrupted chromic catgut. Fascia brought together in a different longitudinal plane and sutured with continuous catgut. Skin closed with subcutaneous silkworm gut or continuous plain catgut. Dry sterile dressing and bandage applied. A seton drain may be left in the joint at the lower end of the incision for forty-eight hours. Care should be exercised not to insert anything but the gloved fingers into the joint, all manipulations being carried out with instruments alone if possible.

Routine After-Treatment.

The administration of 15 to 20 gr. of urotropine per day should be commenced forty-eight hours before the operation and continued for four to five days after.

The treatment of post-operative pain and the bowels should be governed largely by the indications in the individual case. Our routine has usually been to give ¼ gr. of morphia subcutaneously before the patient has come out of ether. The bowels ought usually to be opened by a saline the night after the operation.

Patient should remain in bed at least one week.

Stitches removed and passive motion begun on the eighth day.

The arc of motion should be increased daily, and as a rule 90° may be obtained on the fourteenth day, at which time hot fomentations are ordered twice a day, with massage to thigh and calf. When 90° of motion is obtained, the patient may be allowed to bear weight on the leg.

Stimulation (hydrotherapy and massage) is kept up as long as indicated. Flannel bandage worn from ankle to mid-thigh for one month.

The following cases are grouped according to their pathology and clinical diagnosis for the sake of convenience in describing their surgical treatment.

LIPOMATA.

(Female Cases.)

CASE 1. M. C., female, twenty-one, single. Operation, May, 1902.

Five-inch incision over outer side of left knee. Lipoma found attached to top of external condyle of femur and around the margin of the supra-patellar pouch. Blood supply from the periosteum through numerous small capillaries. Bleeding was checked with hot water. Capsule closed with silk sutures. Recovery was uneventful.

CASE 2. S. C., female, twenty-two, married. Operation, June 23, 1902.

Semilunar incision made over inner aspect of right knee. A sessile tumor was found which varied in color from a gray to brownish-white. Also several short finger-like processes were found, all attached by short pedicles. That portion of the tumor mass which habitually came between the apposing bony surfaces was tough and fibrous in nature.

The leg was put up in a plaster of Paris cast in a position of slight flexion for three days.

Motion of knee was normal on the twelfth day. A slight increase in the size of the joint is present, however, and is possibly due to weight-bearing before it was indicated.

Recovery was uneventful. Discharged July 5, 1902.

CASE 3. M. C., female, thirty-two, married. Operation, Feb. 13, 1903.

Left knee. The pedicle of the lipoma extended so far to the inner side of the joint that it was necessary to open on both sides of the patella. The lipoma was situated in the lower, outer portion of the joint and attached to the synovia posteriorly. A small part of the pedicle was not excised, and difficulty was encountered in checking the oozing.

Posterior wire splint used. On the thirteenth day 50° of motion was obtained, with pain. On the sixteenth day fluctuation was obtained on either side of the patella. Patient complained of some pain and tenderness, but there was no local or general temperature. Condition probably represented a recurrence of oozing into the joint from passive motion, too much forced. Four days later, under anesthesia, joint was opened and about 150 ccm. straw-colored fluid obtained containing a small amount of fibrin. Culture negative. Wound was closed tightly. Stitches were removed on the fifth day and routine post-operative treatment again instituted, with subsequent rapid recovery of normal function.

CASE 4. A. A., female, twenty-six, married. Operation, March 4, 1903.

Incision made over outer side of right knee. Membrane of joint was normal in that portion where fringes are usually present. A small mass, size of silver dollar, was found in the upper outer portion of the joint cavity, punched out in appearance and difficult to distinguish from the wall of the joint. It resembled cicatricial tissue, suggesting a former infectious condition. Seven days later the patient had an attack of tonsillitis of three days' duration, which was accompanied by some pain and tenderness in the knee-joint.

Post-operative treatment was delayed somewhat owing to the above-mentioned infection.

CASE 5. E. G., female, thirty, single. Operation, March 13, 1903.

Incision made over outer side of left knee. When capsule was opened the lipoma was immediately exposed to view and very easily removed. Patient had completely recovered in eighteen days and has had no return of symptoms up to present time (1909).

CASE 6. C. F. H., female, sixteen, single. Operation, March 20, 1903.

When left knee was opened about an ounce of fluid was obtained. Numerous hypertrophied fringes were found throughout the joint, and were remarkable for their extreme vascularity. All the large vessels were tied with silk, yet considerable difficulty was experi-

enced in controlling the hemorrhage. Plaster of Paris bandages applied with the leg in extension.

The night following the operation, temperature rose to 102°; pulse, 120; respiration, 30. Complained of some pain in knee. Temperature and pulse remained around this point for three or four days, and the condition indicated the "lighting up" of an infection already present rather than the introduction of infection at time of the operation.

Stitches at lower angle of the wound were removed on the fifth day and considerable pus with bloody fluid escaped. Wick was inserted under anesthesia. Two days later a staphylococcus culture was obtained from the discharge. Wound was irrigated daily and wick reinserted. A few days later it was found necessary to open entire wound and irrigate the joint throughly. The edges were then only roughly approximated with silkworm gut. On the ninth day the appearance of the wound had improved and general septic symptoms had subsided. Improvement continued up to the twenty-sixth day. Sinus closed in rapidly and was immediately followed by sudden rise of temperature similar to preceding attack. Under anesthesia sinus again opened and 2 oz. of bloody fluid was evacuated from a pocket, following which procedure sinus again began to close and purulent discharge changed to a simple serous ooze. Granulations required several applications of silver nitrate. On the forty-fifth day 90° of motion was easily obtained under anesthesia, followed by an increase in discharge of bloody fluid from sinus and considerable pain.

Patient discharged home on the fifty-seventh day after the first operation. Instructed to continue regular post-operative treatment and report for another manipulation in ten days. No pain at that time but only 15° voluntary motion.

Good function had been secured two years after the discharge from the hospital.

Case 7. M. D., female, forty-three, married. Operation, May 27, 1903.

When joint was opened several small purple fringes were found, also bony exostoses situated on the edge of the articular aspect of external femoral condyle, all of which were removed. Suprapatellar pouch closed by adhesions and joint cavity very small. Pre-operative diagnosis, osteo-arthritis of right knee and ankle. Convalescence normal. Discharged July 6, 1903. Stay in hospital prolonged by ankle condition.

Case 8. M. A. L., female, forty-seven, married. Operation, Sept. 16, 1903.

Incision over outer side of knee-joint. One large lobulated lipoma (size pigeon's egg) was found immediately under the capsule. Removed.

Convalescence rapid and uneventful.

March 27, 1905, excellent functional result.

Case 9. H. K., female, twenty-six, single. Operation, Sept. 20, 1903.

When the capsule was opened, numerous lipomatous villi were found scattered over the anterior aspect of the joint, most of which were removed.

Discharged Oct. 6, 1903. Motions of knee normal, but slight tenderness persisted for some weeks.

Case 10. E. M. F., female, twenty-seven, single. Operation, Oct. 14, 1903.

Incision made over both sides of right knee. Capsule thickened and several lipomatous fringes were found situated under the patella, patellar tendon and on the posterior wall of the joint, all of which were removed with scissors. Left knee opened and a similar although less marked condition found. Ten days later patient had slight temperature, but no knee symptoms. At the same time she had irregular catamenia.

Oct. 24. Right knee swollen and edematous, but there is no marked tenderness or surface temperature.

Oct. 26. Temperature 101.2° with increasing tenderness. Under anesthesia right knee was opened and 4 oz. of yellow fluid was evacuated containing some blood clots. Knee was thoroughly irrigated and wick left in lower angle of wound.

Culture negative. Left knee manipulated at same time.

Oct. 28. Right knee again opened, this time on each side, and wick passed through the joint. No pus found.

Patient underwent a vaginal examination. Suspicion of a Neisser infection could not be verified by microscope.

Nov. 3. Ulcer between buttocks.

Nov. 11. Patient vomited several times. Abdomen was distended and very tender. Temperature normal.

Nov. 12. Ulcer very angry looking. Abdomen examined and diagnosis deferred by surgeons. Advised K. I. gtts. x, t. d., in increasing dosage.

Nov. 16. Recurrence of vomiting. Slight tenderness over gall bladder. Edema of abdominal wall. Knee condition markedly improved.

Nov. 22. Patient coughing and expectorating a white sputum. Negative tubercle bacilli, but hypostatic condition present in the lungs.

Nov. 26. Plaster of Paris applied to right leg to allow patient to lie on side, owing to lung condition. Motion of left knee quite free and painless. Ulcer over buttocks very much improved.

Dec. 6. Patient has complained for several days of pain in the right knee, over external condyle. No objective symptoms present, however.

Dec. 31. Both knees can be flexed to a right angle. A second small ulcer has made its appearance upon the buttocks. Old ulcer at a standstill. Patient has been up and about on crutches.

Jan. 5, 1904. Began this morning to have discharge from right knee. Subluxation has been gradually increasing for past six weeks resulting in genu valgum deformity. Ulcers on buttocks have been suspected of being of an atypical specific nature. Antisyphilitic treatment instituted.

Jan. 19. Patient in poor general condition. Urine shows numerous hyalin and granular casts.

March 28. Patient has continued in about the same condition since last note. Has had several exacerbations in the knee which would clear up in a few days.

April 1. Discharge from soft parts under popliteal space and from upper calf. Incision made over abscess and about ½ oz. of green pus evacuated.

April 5. Leg amputated 7 inches above knee, by Dr. J. C. Munro.

April 28. Patient doing well to date, but slight discharge from inner side of stump noted to-day. Staphylococcus aureus culture.

May 1. No discharge noted to-day.

May. 25. Discharged home using crutches. General condition fair.

Dec. 1, 1909. Using artificial limb and gets about fairly well. Left knee has normal motion.

Case 11. M. K., female, twenty, married. Operation, Oct. 4, 1903.

Left knee-joint opened along inner border of patella. About 2 oz. of fluid evacuated, containing flakes of fibrin. Several fringes found hanging from under surface of patellar tendon, but patellar cartilage everywhere normal.

Convalescence uneventful.

Discharged Nov. 1, 1903.

Case 12. M. B., female, twenty, single. Operation, Nov. 4, 1903.

Right knee opened on inner aspect of joint. No

excess of fluid. Capsule thin. Several large fringes found attached under patella and along both borders of patellar tendon, necessitating an incision over outer side of joint for their complete removal.

Nov. 17. Only 40° of motion present, so leg was manipulated under anesthesia and adhesions broken up. Convalescence rapid after this procedure.

CASE 13. M. McK., female, twenty-two, single. Operation, Dec. 5, 1903.

Incision over external aspect of right knee. Immediately under the external lip of incised synovia were found four venous varices about the size of peas. Surface of membrane embracing same was removed and raw surface seared with cautery. Three silk ties found necessary to prevent venous oozing. From underneath the upper angle of the wound a large fatty tumor protruded its free end. This had a fan-like attachment over the synovial membrane covering the patella, spreading out as far as its external reflection and bound to its attachment in several places by firm fibrous bands. The previous symptoms in this case were probably due to the varicosities and not to the lipoma, and might easily have suggested a phlebitis.

Dec. 28, 1903. Good motion. Can actively extend leg to normal. Flex to right angle. Discharged home.

Three years after there was excellent motion and no recurrence of knee symptoms.

CASE 14. A. M., female, forty-eight, married. Operation, Jan. 20, 1904.

Left knee opened on inner side. One lipomatous growth found adherent to internal alar ligament by a broad base, and two other similar fringes found attached to under surface of patella.

Right knee opened and two growths similar in size and origin removed.

Jan. 23. Pain, especially in left knee, since operation. Both knees examined. Scar of left found inflamed at its lower angle.

Jan. 27. Stitches removed from right knee. Wound clean. Left knee discharging slight amount of pus from above-mentioned area.

Jan. 31. Patient has been having a temperature for the past two days of about 102°. Last night it reached 105°, and was followed by a chill and fall of temperature in six hours to 101.5°. Patient was much exhausted in the morning and presented a marked septic appearance.

Under anesthesia old incision was opened and a counter-incision made on opposite side. No pus found. Joint thoroughly irrigated and wicks inserted.

Feb. 1. Local conditions appear satisfactory, but patient has failed rapidly since the operation, various stimulating measures resorted to with no more than temporary relief.

Feb. 2.[2] Mild delirium throughout night. At 6 A.M. temperature by axilla 106.4°; at 7 A.M., 107. Patient died a few minutes later.

CASE 15. L. M. B., female, ten. Operation, Feb. 29, 1904.

Incision over inner aspect of left knee. A portion of the semilunar cartilage was found partly detached from its normal connections, being joined to the head of the tibia by a few fibers from its circumference and partly separated from the remaining cartilage. This portion of cartilage was removed, together with a small lipoma which was found attached to the internal alar ligament by a slender pedicle. The tumor was pyramidal in shape, with a smooth, even surface and adherent over part of its extent to the synovial membrane below the patella. No ties were required.

Plaster of Paris was applied with the knee in complete extension.

March 11, 1904. Cast removed. Motion in flexion about 30°, with pain. Discharged with directions for manipulation later.

CASE 16. A. LeB., female, nineteen, single. Operation, May 13, 1904.

When capsule was opened on inner side of right knee there escaped about ½ oz. of deep red, serous fluid, indicating an old hemorrhage. Several sessile lipomata found over upper and inner aspect of joint, forming in reality a single mass the size of two thumbs placed side by side. These were quite easily removed.

May 28. Patient discharged. One hundred degrees of flexion possible, with some pain.

CASE 17. H. A. C., female, twenty-two, single. Operation, Oct. 17, 1904.

Incision made over outer side of right knee. Several fatty masses were removed, most of which were attached to the anterior surface of the joint above the patella. They were easily dissected away, leaving normal synovial membrane.

Left knee was operated upon in a similar manner. Fatty masses were smaller than those found on the right side.

Oct. 20. Right knee became septic, and when stitches were removed entire wound broke open and a quantity of yellow pus evacuated. Three drains left in joint after thorough irrigation.

Nov. 4. Temperature and pulse continue elevated and knee was again opened, considerable pus obtained and few adhesions broken up.

Nov. 14. Patient in very poor condition. Circular incision connecting lower angles of former incisions. Patellar tendon cut and pocket of pus found directly underneath. Crucial ligaments and external lateral ligament cut, revealing a second pocket of pus. After thorough irrigation, leg was placed on posterior wire splint.

Nov. 24. Patient died from general septicemia.

CASE 18. M. H., female, twenty-nine, single. Operation, Jan. 11, 1905.

Through an incision on the outer side of right knee-joint the capsule was found somewhat thickened. A diffuse lipoma was present in the anterior lower quadrant of the joint surrounded by numerous fringes, all of which were removed.

Jan. 27. Convalescence uneventful. For past six days passive motion beyond a right angle.

CASE 19. M. A. R., female, eighteen, single. Operation, June 16, 1905.

Incision over outer side of left knee. When joint was opened a sessile lipoma was found directly under point of incision filling up the pocket beneath the patellar tendon, attached to the ligamenta alaria and reflected upon the edges of the external lateral ligaments.

June 18. Considerable swelling about the joint and a thin, bloody, purulent fluid drained from the lower angle of the incision.

Joint again opened up under anesthesia and found infected. Counter-incision made, irrigation with Harrington's solution followed by salt solution; two drainage tubes were left in the joint cavity.

July 13. Gradual improvement in knee and general condition.

Discharged against advice.

Some permanent deformity and stiffness.

CASE 20. D. A., female, thirty-six, married. First operation, March 16, 1906.

Patient was operated upon for villous arthritis of ankle. Lipomatous growths removed from tendons and sheaths below external malleolus.

Discharged March 26, 1906.

Second operation, Dec. 14, 1906. Telangiectatic hemangioma. See report of case by Dr. A. T. Legg.[1]

[2] This case was probably infected from a case of osteomyelitis operated in the same room at the same time. Culture same from both cases.

[1] BOSTON MED. AND SURG. JOUR.

Incision over outer aspect of left knee. Lipoma of solitary type protruded when capsule was opened, attached at edge of patella, 1 inch by 1½ inches in size, yellow, lobulated and flattened.

Dec. 19, 1906. Patient complains of considerable pain, especially at night, since operation. Stiff knee on sixth day, and considerable pain when any passive motion was attempted. Patient refuses to co-operate in the treatment in any respect.

Discharged Dec. 24, 1906. Advised to rest at home one week and then begin massage and passive motion. Good result eventually obtained through the efforts of a masseuse.

Case 21. E. W., female, twenty. Operation, March 30, 1906.

Incision over outer side of left knee. A band of fibrous tissue was seen extending well into the joint between its apposing surfaces, which was carefully dissected out. A bony spur which was found on upper surface of inner tuberosity of the tibia was also removed.

April 11. Patient doing very well. Discharged home.

Case 22. M. C., female, thirteen, single. Operation, July 20, 1906.

Incision over outer side of right knee. In exposing joint cavity one large fringe and three small ones were seen extending in under the patella. These were removed.

Convalescence progressive and uneventful.

Discharged Aug. 1, 1906.

Case 23. M. M., female, sixteen, single. Operation, May 24, 1907.

Knee opened on inner side. One large fringe about 1 inch by 1½ inches found attached by pedicle and several smaller fat "tabs," all of which were removed.

June 1, 20° of motion with pain.

June 5, 50° of motion with pain.

June 6, discharged, 10° more motion than at last note and no pain experienced.

Case 24. T. McK., female, thirty-two. Operation, Jan. 3, 1908.

Left knee opened over outer anterior aspect. Synovial membrane thin and a large collection of fat forming a sessile tumor size of an English walnut encountered between the synovia and fibrous capsule. This mass, together with its synovial attachment, was removed. Remaining portion of joint apparently normal, except for a small eroded area on the under surface of the patella, apparently covered by the lipoma which acted as a pannus.

Jan. 20. Ten degrees of free motion with pain, but limited beyond this point.

Jan. 22. Under light anesthesia leg was flexed to a right angle and very little resistance was encountered.

Jan. 25. Mechanical obstruction seemingly removed, but passive motion is attended with great pain.

Feb. 7. Flexion beyond a right angle painful. Active motion in extension limited, but slow manipulation overcomes this.

Improvement has been slow but progressive.

Discharged home.

Case 25. E. B. M., female, twenty-nine, married. Operation, Jan. 15, 1908.

Incision over outer side of knee. Joint opened through bulging capsule directly over lipoma. Synovia thin. Tumor removed. Remaining portion of joint normal in appearance.

Post-operative treatment progressive to seventh day, when patient began her menstrual period, accompanied by intense dysmenorrhea, temperature of 102° and pain in knee.

Jan. 25. Two days after last note, all symptoms in knee completely disappeared. A few degrees of motion.

Jan. 29. Under anesthesia knee was forcibly flexed beyond a right angle. Little force required up to this point. After ether recovery patient was able to bend knee without pain as far as bandages would permit.

Feb. 2. Motion free to 50° in flexion, beyond which there is a feeling of tension. Walks without any discomfort.

Discharged home.

Case 26. L. E. C., female, twenty-two, married. Operation, Feb. 10, 1908.

Incision over inner aspect of left knee. Capsule very vascular; very little subserous fat. When joint was opened numerous villi were found throughout almost the entire cavity, expecially about ligamenta alaria. Quadriceps pouch small and contained some viscid exudate walled off by adhesions. Many of the villi which were removed had undergone fatty degeneration. Cartilage presented normal appearance. No excess of fluid in joint.

Feb. 17. No temperature. Motions of knee free.

Feb. 20. Discharged home.

April 15. Patient entered Out-Patient Department complaining of pain in both feet. No knee symptoms. Physical examination; Marked prominence of internal malleoli, characterised by swelling and some capsular thickening. Peroneal spasm.

July 7. Feet improved, but right knee swollen and contains fluid. Villi plainly palpable. Condition of left knee good.

July 8. Patient again operated upon. Incision over inner side of right knee. Many red villi found and a red pannus extending over inner half of joint. A small spur on inner trochlear surface of femur was noted projecting through pannus. A small eroded area found over external trochlear surface. Considerable loose fibrin in the joint. A small part of the thickened capsule was excised.

July 28. Discharged home. Uneventful recovery. Motion of left knee normal and right much improved.

Sept. 4. Patient steadily improving. Knees can be extended nearly to normal.

Jan. 1, 1909. Patient under treatment with enemata and buttermilk. Condition improving.

Case 27. A. D., female, eighteen, single. Operation, May 1, 1908.

Right knee-joint opened over inner aspect. When capsule was incised, 1 oz. of yellowish fluid escaped. Many villi present, all of which were excised.

May 21. Discharged. Knee can be actively flexed to a right angle. Walks without difficulty or pain.

Discharged home.

Jan. 1, 1910. Patient has had neither recurrence of symptoms nor any difficulty with the joint since last note.

Case 28. C. K., female, nineteen, single. Operation, July 1, 1908.

Joint opened over inner aspect. Beneath capsule and slightly to inner side of patella was a lipomatous mass one inch in diameter, which was easily removed.

July 28. Recovery rapid. Motions of knee good.

Discharged home.

Case 29. S. F., female, thirty-one, married. Operation, Nov. 25, 1908.

Left knee-joint opened over both inner and outer aspects. Joint cavity contained a small amount of brownish fluid. A small lipoma situated underneath patella was removed, and another small fatty tumor was removed from the upper portion of the quadriceps pouch.

Plaster of Paris bandages applied with leg slightly flexed.

Nov. 30, 1908. Cast split. Small amount of post-operative synovitis is present. Twenty-five degrees of motion in flexion.

Dec. 4. Operative synovitis persists. Patient has had more pain than the average case, and recovery is not as progressive as usual.

Discharged against advice.

Six months later patient has not regained full muscular power of her leg, and continues in poor general health. There is question of incipient pulmonary tuberculosis.

CASE 30. L. U. C., female, twenty-two, single. Operation, Dec. 14, 1908.

Incision over outer side of left knee. No excess of fluid found. Lipoma larger than usual and attached by three fibrous pedicles to the top of the external femoral condyle and to parietal synovia. In size, 2½ by 3½ inches thick, very vascular and not apparently covered by synovial membrane. Nourishment supplied chiefly from the parietal membrane. When pedicle was exposed, larger vessels were tied before being cut, and even then, when tumor was excised, several bleeders had to be tied off. Silk seton left in lower angle of wound three days.

Patient had considerable pain for several days following operation.

Dec. 24. Can flex leg 30° without pain or much discomfort. Discharged.

July 9, 1909. Patient complains of pain in extending leg from a position of 40° flexion. Massage and baking have not brought much relief.

Oct. 14. Possible non-removal of entire tumor, recurrence of same or growth of another from a near-by site may account for present condition. There are, however, less marked symptoms now than in pre-operative condition. Patient is wearing kneecap during the day.

Nov. 1. Condition improved. Less pain on extremes of motion than has hitherto been noted.

CASE 31. M. D., female, thirty-six, married. Operation, Oct. 13, 1909.

Incision over inner aspect of right knee. Pedunculated lipoma size of hen's egg found attached under patellar ligament. Removed.

Oct. 26. Fairly rapid return of motion.

Discharged home.

CASE 32. R. B., female, twenty-one, single. Operation, Dec. 1, 1909.

Left knee opened over outer anterior aspect. Lipoma attached by pedicle underneath lower border of patella and tendon.

Dec. 10, 1909. Passive motion to 45° in flexion.

Dec. 15. Flexion to 90° with some pain.

Dec. 20. Discharged home.

Dec. 29. Full extension. Active flexion to right angle. Passive, 20° beyond a right angle, accompanied by some pain.

CASE 33. E. D., female, twenty-eight, married. Operation, Dec. 22, 1909.

Both knees opened over external aspect. Large solitary lipomata found in each joint similar in size and position, subsynovial, and situated in outer, lower quadrant.

Dec. 31. Motion as far as bandages will permit, without pain.

Jan. 17, 1910. Motion in right to beyond right angle. In left, to a right angle. Walking without support.

CASE 34. A. M., female, twenty-three, single. Operation, Dec. 29, 1909.

Right knee-joint opened over outer aspect. Large amount of fluid in the joint. Large lipoma-like growth was found attached by pedicle to external aspect of patellar tendon. The villous tip had quite a little fibrin adherent to it.

Dec. 31. No temperature or pain.

Jan. 10, 1910. Normal motion in the knee. No swelling.

Discharged.

(To be continued.)

THE SMALL FIBROUS PROSTATE.*

BY ARTHUR L. CHUTE, M.D., BOSTON.

THE occurrence of several cases of small fibrous prostate relatively recently has directed my attention especially to this subject and has impressed upon me the fact that this type differs in certain respects from the large prostate that we commonly see. The actual dangers to life are the same as those seen in the hypertrophic gland, but the findings on examination, and the treatment these prostates require, quite warrant us, I believe, in considering them as forming a class by themselves. I believe that to variations of this condition are to be ascribed a good many of the more obscure obstructive conditions, such as contractures of the bladder neck, bars at the bladder outlet and some at least of the cases of "prostatism without prostate" or "obstruction without mechanical obstacle."

I shall give short abstracts from several of my cases that illustrate the points that I wish particularly to bring out.

CASE I. A man, forty-seven years old, seen about three years ago. He had passed several small stones, the first eleven years before, the last three years before. For three years he had had frequent and painful urination. His disability had been such that he had been unable to work a considerable part of the time. He had to get up from two to eight times at night — stream small and without force. He had to strain hard to urinate. His prostate was not increased in size. A large stone was seen in his bladder. The stone was removed by suprapubic cystotomy. I could see no jutting of the prostate into the bladder at the time of operation. There was a recurrent suprapubic sinus and a turbid urine following this operation. Four months after operation he returned and I found a turbid residual of 8 oz., as well as a small phosphatic stone. I removed by a perineal operation a small amount of dense prostatic tissue, also the stone. He appeared four months later without urinary symptoms and with a transparent urine. I have heard from this man several times since and he remained well at the time of the last report.

CASE II. A man of fifty-two whose urinary symptoms began seven years before. He was troubled chiefly with pain, frequency and a turbid urine. Occasionally he had chills and pain in his left kidney region. He passed urine with moderate frequency during the day and from three to five times at night. He sat down to urinate when he could, as the straining necessary to urination occasionally caused his bowels to move. He had a retention of some hours' duration on one occasion. He had had considerable local treatment of his bladder without relief. He had a turbid residual of ½ oz. No definite prostate could be felt by rectum. His prostatic urethra was very sensitive, and the reaction after the passage of sounds caused even greater difficulty in urination. I removed by perineal operation a small amount of very dense prostatic tissue, estimated at a little over a dram in weight. In attempting to bring the prostate into the field the tractor tore through the bladder outlet on one side, a thing that was looked upon as unfortunate at the time. It is, however, probable that this was an important factor in bringing about his good functional result. About three weeks after his prostatectomy this patient had an attack of pain in his right loin accompanied by chills. There was a tender mass. A small shrunken pyelonephrotic kidney was

* Read at the annual meeting of the American Urological Association in St. Louis, June 6, 1910.

removed. This man at last report, some two years after operation, had had no recurrence of his symptoms, though his urine was not entirely clear.

Case III. A man, fifty-four, who had a perineal section and drainage in the summer of 1908. This was done partly because of pain, frequency and turbid urine, and partly as a diagnostic measure. He had, following operation, a troublesome perineal sinus that had to be curetted. In March, 1909, he came under my care because of the illness of the gentleman who had previously operated upon him. He was having a considerable temperature with tenderness over his right kidney, evidently an ascending infection. His prostate was not increased in size, but was fibrous. Soft rubber and woven catheters were caught and held at the bladder outlet, while a curved instrument entered his bladder fairly easily. There was a residual on various occasions of from 6 to 13 oz. The amount apparently depended upon whether he had had a large sound passed recently or not. The cystoscope showed a deep anterior commissure, but nothing more. The diagnosis of a band or bar at the bladder outlet was made and his bladder opened above the pubes. A little fold of mucous membrane that was found blocking the bladder outlet was divided with a cautery. He made a fair convalescence and has been better, but when seen last a few days ago still had a turbid residual of 8 oz. In this case I overlooked the underlying process, the small fibrous prostate.

Case IV. A man, fifty-seven, on whom I did a perineal section for a filiform stricture of the deep urethra in May, 1909. As he had had chills at intervals for some years and had a turbid urine, I drained his bladder for a time. At the time he left the hospital he emptied his bladder completely and had a urine that was nearly transparent. In the summer of 1909 his urine again became turbid and I found a residual of 2 oz: In spite of the use of a catheter and bladder washings, I found in December, 1909, that his residual had increased to 4 oz., though his urethra took a 26 F. sound. He presented a prostate that was not enlarged, but was fibrous, with a definite marking of the commissure or isthmus between the lobes. In January, 1910, he again had chills. In February a perineal operation was performed and all the prostatic tissue that I could trim away was removed. This tissue only weighed a dram and a quarter. The bladder outlet was very tight and fibrous. I dilated it very considerably, but did not incise it as I should have done. This patient made a good recovery, but three months after operation had a residual of 1 oz. of slightly turbid urine. He also has had a slight chill on one occasion after the passage of instruments.

Case V. A man of sixty-nine whose urinary trouble dated back about three years, and had been increasing gradually. He had a residual of from 2 to 3 oz., with rather frequent urination, especially at night. He had passed a catheter occasionally, but for a time had been unable to do this. His greatest complaint was of perineal discomfort, that was worse when he was on his feet; as a result he spent most of his time lying down. His prostate was little, if any, increased in size, but was dense and fibrous, with a well-marked sulcus. Perineal prostatectomy was done and about 2 dr. of very dense tissue removed. The bladder outlet was felt to be a dense fibrous ring — this was well dilated. When the perineal tubes were removed this patient was unable to pass urine, and his bladder distended to above the pubes. A retention catheter was used for a few days, but when it was removed the same state of affairs recurred. At a second operation I removed a few bits of prostatic capsule and a very little prostatic tissue. I also slit the bladder outlet on each side for about a half an inch, fearing to cut it on the floor because of the disturbed relations following my earlier operation. There has been no difficulty in emptying his bladder completely since the second operation. On the contrary, at the present time, one month after operation, he has some incontinence, but his control seems to be gradually returning and I believe in time that it will be satisfactory.[1]

Case VI. A man of sixty whose bladder symptoms began about ten years ago. Two years ago a large stone was removed by a suprapubic incision, and a small median bar was incised at the same time. Following this he had relief for a time, but his symptoms gradually recurred until he spent a large part of the day and night with a catheter tied into his bladder. In the morning, after removing his catheter, he could pass a little urine, but by noon his ability to urinate would be lost and he would be forced to replace his catheter, and spend the rest of the day on a couch. By rectum I could feel absolutely no sign of any prostate. Cystoscopically there was a marked anterior commissure and a slight jutting into the bladder of both lateral lobes. A perineal prostatectomy was done April 25, 1910. I was able to remove by the use of curved scissors and rongeur forceps 2 dr. of fibrous tissue. The sharp unyielding ring of the bladder outlet was cut down to the floor and a lateral incision was made on his left. This man passed all his urine by urethra on the fifteenth day after operation. A catheter showed that he emptied his bladder completely. His urine was clearing up when he left the hospital three weeks after operation.

I have seen a number of other cases of this type, but these are the most typical and illustrate the points that I wish to bring out which refer particularly to the etiology, diagnosis and treatment of these small fibrous prostates.

Macroscopically these prostates present at operation a dense, fibrous, almost cartilaginous condition and do not show the least tendency to form enucleable tumors such as we see in the hypertrophic cases. There may be places where the tissue is a little denser than in others, but this is not marked, and the consistency seems, on the whole, homogeneous. The amount of tissue that one removes in such cases is always small. I think the largest amount that I have removed from a prostate of this sort has been about 5 dr.

Some of the earlier prostates of this sort that I operated upon were not examined microscopically. The later ones have all been. They have shown a hyperplasia of the glandular elements, sometimes very marked. There has been an infiltration of the periglandular tissue with lymphocytes, plasma cells and, in some places, small round cells. In some there has been an increase of connective tissue throughout the gland which has compressed and distorted the ducts and acini. I do not know, but I suspect, that there has been a diminution of the muscle fibers.

The microscopical picture, then, has been that of a low-grade inflammation, to be compared with what we see in hyperplastic endometritis, for instance.

I formerly was of the opinion that some definite inflammatory invasion of the gland, probably in most instances a gonorrheal infection, was the

[1] At the present time this patient has perfect control.

underlying cause of these small fibrous prostates. Undoubtedly many of these cases will have a history of a previous gonorrhea, and I believe that the small fibrous prostate in some instances represents the end result of a gonorrheal prostatitis. We must, however, admit that other causes serve to bring about the condition quite as well as a gonorrheal infection. In only three of the reported cases was there a history of a gonorrhea, while in an equal number there had been no urethral infection. This raises the possibility that the previous gonorrhea may not have been the cause of the fibrous prostate, even in those patients who had suffered from gonorrhea. In searching for a probable cause for the small fibrous prostate, in the cases that have had no urethral infection, I have been unable to find anything that would serve as a reasonably probable etiological factor. In none of the cases had there been a history of anything like an acute prostatitis. It seems probable from the histological appearance that the process depends upon some very mild infection — without a doubt not of venereal origin. Very likely these infections may be brought by the circulation. The theory that they are infections from the rectum by way of the lymphatics hardly seems probable to me. If from the rectum, the infection would probably be with the colon bacillus, and I shall expect that the acute invasion would be attended with distinct symptoms.

The diagnosis of this condition can be most puzzling, especially if one has not yet trained himself, in all prostatic cases, to consider the "obstructive" rather than the "hypertrophic" element. If one demands a prostate that is enlarged by rectum as an essential part of every picture of prostatic obstruction, these cases will naturally be most puzzling. If, on the other hand, one sees in every man who has difficulty in urination the possibility of an obstructive prostate, there is much less difficulty.

When a urinary obstruction that depends upon a small fibrous prostate has not progressed beyond the first stage, that is, while the bladder is still able to completely empty itself, and the symptoms are mostly those of bladder irritation, the diagnosis is difficult and may require very close study. Case II, where the residual was only ½ oz., a negligible quantity, was of this type and the cause of his symptoms had been overlooked by several men. Occasionally in these cases one may feel by rectum practically no prostate at all, as in Case VI. More often, however, one feels a small but clearly defined fibrous-feeling gland, with a well-marked sulcus; though the prostate is not enlarged, this condition may be considered definitely abnormal and suggestive of the possibility of obstruction. If such a patient presents, in addition to his symptoms of bladder irritation, a marked resistance to a soft catheter just at the bladder outlet, the condition is highly suggestive. The passage of a sound will often allow one to feel with great ease the gripping of the instrument by the contracted bladder neck. Some of these patients, with obstruction due to a small fibrous prostate, get temporary relief from the use of sounds, for with them the obstruction to urination is not from a raising or deformity of the bladder outlet, but is from a lack of distensibility of the outlet. This lack of distensibility of the bladder outlet is due to the ring of fibrous prostatic tissue that has been almost shrunken-on, about the beginning of the prostatic urethra.

In the doubtful cases a cystoscopic examination of the bladder outlet will often be of help in arriving at a correct diagnosis. The prostate may be seen to bulge back into the bladder a little on the sides, or the anterior commissure may be very marked. Occasionally it will be seen that the bladder outlet is a little raised above the level of the trigone. The bladder wall will often show bundles of hypertrophied muscle fibers, a sign that the bladder has met with unusual resistance in its attempt to empty itself. Exclusion will, however, often have to play a considerable part in arriving at a correct diagnosis in the cases that do not as yet show a residual.

When there is a residual urine, the diagnosis is much easier. I feel that, broadly speaking, if one can rule out stricture, a lesion of the spinal cord or a diverticulum of the bladder, he may assume that the cause of any residual urine lies in some abnormality of the prostate. I include under the term abnormality of the prostate not only the hypertrophic and fibrous prostate, but also the bars at the bladder outlet, and contraction of the bladder neck, since I believe that they are almost without exception dependent upon fibrous changes in the prostate and are to be considered as part of the prostatic process.

Here I wish to make a slight digression in support of this opinion. With possibly a few exceptions due to a hyperplasia of misplaced prostatic tissue, we must either assume that the bars at the bladder outlet are congenital, in which instance it is hard to explain why they are symptomless over a long period of time, or we must assume that they are produced by some change in the immediate neighborhood. With a marked microscopical change in an organ lying in immediate proximity, it seems to me fair to assume that the abnormality probably depends on this change. The probability of this seems heightened when we consider the joint action that the bar and prostate seem to play in bringing about the obstruction in some of these cases. Cases III and VI illustrate this very well. As regards the contracted bladder outlet, it is hard to believe that an hypertrophy of a weak muscle, such as we know the internal sphincter to be, can produce such a dense and unyielding ring as we sometimes see in these cases. It likewise seems improbable that any thickening of the mucous membrane alone would be likely to bring about such a result. On the other hand, a circle of fibrous prostatic tissue sunk into the angle of junction of the bladder and urethra would produce just such a thick, firm ring. Those who have dealt with this type of prostate know how dense this tissue is, and how intimately it attaches itself to the mucous membrane.

The cases, then, in the second and third stages

of obstruction present little difficulty in diagnosis if one will bear in mind that one can have a prostatic obstruction without an appreciable increase in the size of the gland as felt by rectum. Any obstruction that does not depend upon an hypertrophic prostate or new growth must depend upon a fibrous prostate, or one of the conditions that it produces.

We have two other forms of prostatic diseases that may be confused with the fibrous prostate — tuberculosis and carcinoma of the prostate.

In tuberculosis the gland rarely has the clear-cut, hard outline seen in the fibrous prostate. It is usually more tender; often there is a mass in an epididymis or a vesicle, and in all my personal cases tubercle bacilli have been found in the urine. In one or two cases, however, the condition was perplexing at the outset.

It is often difficult, and sometimes impossible, to differentiate between the small fibrous obstructive prostate and the early stage of a carcinomatous prostate. The question of malignancy arises in the consideration of many of the cases of this type since the malignant prostate is, as a rule, relatively small and hard, though this is not without its exceptions. When the carcinoma is advanced, the stony hardness, rather than fibrous consistency of the gland, and especially the fixity of the prostate, makes the differentiation easy. In a small proportion of cases I find it absolutely impossible to tell before operation whether a given prostate is of the small fibrous variety or a beginning carcinoma.

Great interest attaches to the treatment of these small fibrous prostates, for I believe it is in this type of obstruction that we meet many of our operative failures or unsatisfactory results. I know this has been my personal experience. The suprapubic enucleation is, in my opinion, quite unsuited for dealing with this type of obstruction. In the only instance in which I have attempted it in this sort of a prostate I found that it was only with the greatest difficulty that I could tear away a small amount of tissue. This gave some relief, to be sure, but an inferior result. The median perineal operation would seem to be as inapplicable as the suprapubic operation, though I must confess that I have not tried it. The transverse perineal operation seems to me the one best suited for dealing with this condition.

As I have studied my cases, and particularly my unsatisfactory results, I have arrived at the conclusion that in these cases one must do more than it is necessary to do with the hypertrophic cases. It is not enough in many instances to simply remove all the prostatic tissue that one can get. This fact is well-illustrated in my fourth and fifth cases. In Case IV, after the removal of all the prostatic tissue that I could get, the patient remains unable to empty his bladder perfectly. In Case V, I was compelled under similar circumstances to do a secondary operation. I believe in theory that if we removed all the prostatic tissue beneath and at the sides of the prostatic urethra, and left the urethra absolutely free of prostate, that would be sufficient. In practice I doubt if this can be done, as there seem to be little bands of prostatic tissue that are fairly sunk into the wall of the urethra. At any rate, after the removal of all the tissue that we can get, there often remains a small tight fibrous bladder outlet, wholly different from the gaping, open bladder outlet seen after the removal of the usual hypertrophic gland. I believe that it is essential that this fibrous ring be split, either by an incision on the floor or by an incision on the floor and on one side. This cutting of the bladder outlet also does away with any slight bar.

In order to meet these requirements I have gradually made certain modifications in the usual transverse perineal prostatectomy that I think are especially adapted for dealing with this condition. I dissect the perineum and lay the prostate bare after the method that Young has so clearly described. Then, instead of opening the urethra just in front of the prostate, I open into the prostatic urethra through the tissue of the prostate itself, at a point just back of its tip. This is done in order that I may avoid any chance of injuring the compressor urethræ, as it is most important that this muscle be left intact if one is to intentionally divide the bladder outlet, including, as this will, the internal sphincter. With the tractor in place, and with the surface of the prostate well exposed, I either make a transverse incision through the capsule, or, making an incision into the substance of the gland, I remove with curved scissors first the exposed surface of the prostate and then all of the prostatic tissue that I can get, below and at the sides of the urethra. I remove the tissue back to where I can feel the tractor in the bladder separated from the prostatic cavity by only the thickness of the bladder wall. In digging away this prostatic tissue I have lately found biting forceps of great service. Their use for this purpose was first called to my attention by Dr. A. T. Cabot. I have had a pair of rongeur forceps, such as are commonly used for the removal of adenoids, made a little less curved and find them useful. I find them quite as useful, however, as a forceps to pick up the dense prostatic tissue as for their biting ability. They can be made to bite into the densest tissue and give one a hold that I have been wholly unable to get with ordinary toothed dissecting forceps or with tenacula of various sorts.

When one has removed all the prostatic tissue that he can get, it is necessary to see if the bladder outlet presents a sharp, tight ring. If it does, this must be cut; a single cut on the floor, well through the band, will, I believe, be sufficient in most cases, It can be supplemented with a lateral cut if desired, or a cut on either side may take the place of the incision on the floor; the point is to leave the bladder outlet open and patulous. I do not believe that incontinence follows this cutting of the bladder outlet, if one leaves the compressor urethræ intact. The incontinence in Case V of my series might seem to contradict this, but I am convinced that this was due to an injury of the membranous urethra that I discovered at the close of the first operation. This

was brought about by the unguarded use of a retractor. The cutting of the bladder outlet has not usually been attended with much hemorrhage. In a case more recent than those described in this paper, I encountered a sharp hemorrhage, but it was perfectly controlled by gauze packing. In this type of prostate the bleeding incident to the removal of the prostatic tissue itself is less than that seen in the large hypertrophic prostates in which there is the increased blood supply commonly seen in tumors in general.

After incising the bladder neck double tubes should be placed in the bladder and brought out through the perineal wound. I usually use tubes having a diameter of $\frac{5}{16}$ inch, sometimes $\frac{3}{8}$ inch. I believe it is well in these fibrous prostates to leave these tubes in place for three or four days, instead of one or two. It has been my custom of late to pass a small rubber catheter into the bladder through the urethra at the time that I insert the perineal tubes, and to fix it by a stitch through the meatus. It seems to hasten the closing of the perineal wound and to facilitate the subsequent passage of instruments if this becomes necessary. This I do not confine to operations on fibrous prostates, but use it in the hypertrophied ones as well.

I lead rubber-covered wicks down into the cavity from which the prostatic tissue has been removed, and, after bringing the fibers of the levator ani together with two catgut sutures, I close the skin wound on either side of the tubes and wicks. While the urine is bloody and contains small clots I have the bladder irrigated; at first at intervals of an hour or two, later at less frequent intervals. The wicks are removed in twenty-four hours.

These modifications of the usual operative technic have gradually been evolved to meet difficulties that I have encountered in dealing with these cases. The method in its entirety has as yet been used in only a few cases, but has given satisfactory results.

The points to which I would call special attention are these:

There is a class of obstructive prostates in which the rectal examination shows little, if any, increase in size of the gland. These prostates are dense and fibrous, showing little similarity to the large hypertrophic prostates. They are the result of an inflammatory process. Their recognition before there is an appreciable residual may be difficult. They are often associated with a contraction of the bladder neck or a bar at the bladder outlet. In order to give these patients relief it is important not to overlook either element of the obstruction.

ANALYSIS OF WOUND INFECTION IN ONE THOUSAND CONSECUTIVE CLEAN OPERATIVE CASES.

BY W. P. GRAVES, M.D., BOSTON.

The development of modern surgical technic has reached a point where, under proper conditions, fatal or even dangerous sepsis following clean operations is, for the most part, eliminated. The troublesome occurrence of wound infection, however, is still sufficiently frequent in public hospital practice to deserve serious attention. In an effort to study the possible means to avoid wound sepsis I have analyzed the present series of cases from my practice at the Free Hospital for Women in in order to establish a basis of comparison for future work, and also to stimulate, if possible, comparative reports from other hospitals. As the avoidance of wound sepsis is unquestionably a matter largely of techincal detail, it is hoped that in this way some useful information may be gained in the solution of a difficult problem.

Each operation was performed from beginning to end by myself, thus establishing the personal equation. The conditions relating to the preparation of the patient, general operating-room technic and post-operative treatment were practically constant throughout the series. The technical treatment of the wound was, in some instances, changed and will be noted later. The chief inconstant factor in the technic was the somewhat frequent changing of operating-room assistants and nurses. The custom of frequently changing assistants which unfortunately generally prevails in the public hospitals of this community is a considerable deterrent to well-organized and systematic surgical work, and probably has some influence in the matter of wound sepsis. How far this is true can only be determined by a comparison with cases from public hospitals where the system of permanent assistants obtains.

The present series of 1,000 cases comprises 574 laparotomies, of which 235 were combined with plastic vaginal operations; 376 uncombined plastic operations, 55 breast operations and 11 miscellaneous. In the list of laparotomies are included inguinal hernias and operations on kidneys. Cases of chronic pelvic inflammatory disease are included as clean cases if they were not running a temperature at the time of the operation. Some of these having sterile pus in the pelvis were temporarily drained through the vagina. Radical operations for cancer of the cervix uteri are also included as clean cases, although operated on in the presence of an ulcerated surface. With an adequate preparation of the ulcerated surface, such operations may properly be included in the category of clean cases. Complete lacerations of the perineum are also regarded as clean cases, although the field of operation is exposed to the mucous membrane of the rectum. Most of the breast amputations and abdominal hernias were drained through stab wounds, a form of drainage which adds no risk of infection, but, on the other hand, as will be seen, is of great assistance in preventing general sepsis of the wound.

Out of the 1,000 operative cases, 51 had some form of wound infection which in all but one case was of a mild form, the organism being a staphylococcus in all instances. Twenty-eight of these infected cases were laparotomy wounds where the infection consisted mostly (19 cases) of slight sepsis of a buried catgut knot, the wound closing immediately after extraction of the knot. Some

of these catgut knot infections did not appear until some time after the patient was discharged from the hospital. The other 9 laparotomy wounds were septic to a greater or less extent throughout the wound. Of these 9 cases of general sepsis in the laparotomy wound, 7 occurred in extensive abdominal hernia wounds and 2 occurred in inguinal hernia wounds. In other words, all the cases of general sepsis in the list of laparotomies occurred in hernia wounds. Nine of the breast wounds were more or less septic, the sepsis of 2 of them, however, being confined to a small area where the angle of a too tightly drawn plastic flap necrosed. Ten of the perineum wounds had stitch abscesses, though none were completely septic. Three of these cases were operations for complete lacerations; 4 were cases of very large thin-walled rectoceles. Of the trachelorrhaphies, one wound failed to unite; of the anterior colporrhaphies, one went septic; of the miscellaneous cases, a plastic on the urethra and an operation on the cervix for anteflexion failed to unite by first intention. The total mortality from all causes in the 1,000 cases was 3. One patient died from shock following a radical operation for cancer of the cervix. The second case with a pre-existing heart lesion died of cerebral embolism following an operation for chronic appendicitis. The third case was operated on for an enormous post-operative ventral hernia. The lower end of the wound became septic. Five weeks after the operation and after the wound had healed, the patient died of a sudden acute endocarditis. The endocarditis was probably in some way the result of the wound sepsis. This case is, therefore, recorded as one of death from sepsis.

Although the cases operated on number 1,000, the actual number of wounds subject to infection was much greater; e. g., a combined plastic and laparotomy case might have, beside the wound of the abdomen, a wound of the cervix, of the anterior vaginal wall and of the perineum. In order, therefore, to determine the exact proportion of sepsis to all the wounds, I have constructed the following table:

Nature of wound.	Number of wounds.	Total number of septic wounds.	Number of wounds with general sepsis.	Total deaths from all causes.	Deaths from sepsis.
Laparotomy,	574	28	9	3	1*
Perineorrhaphy,	499	10	0	0	0
Trachelorrhaphy,	465	1	0	0	0
Anterior colporraphy,	313	1	1	0	0
Miscellaneous,	11	2	0	0	0
Breast,	55	9	7	0	0
Total,	1,917	51	17	3	1

	Per cent.
Proportion of sepsis to cases operated on,	5.1
Proportion of sepsis to all wounds,	2.6
Mortality from all causes,	.3
Mortality from sepsis.	.1

* Acute endocarditis following wound infection.

SEPSIS IN PLASTIC WOUNDS.

A study of this table will show that the figures for the vaginal plastic operations are fairly encouraging. Of the 465 trachelorrhaphies, only 1 became septic, although there are included in this list about 50 high amputations. One of the anterior colporrhaphy operations became septic, the failure in this case being entirely due to a lack of coaptation of the wound edges. It may be said, therefore, that sepsis in operations for laceration of the cervix and for cystocele should be practically eliminated, and that when sepsis does occur, it is due to unskillful approximation of the wound edges. The operations on the cervix for lacerations were all performed according to Emmet's method, and the amputations were performed by Hegar's method. The operations of anterior colporrhaphy were, for the most part, done by the method described by me elsewhere.[1]

Sepsis occurring after perineal operations is, under certain conditions, very difficult to avoid. Three of the 10 cases of stitch abscesses in perineal wounds, recorded in the table, followed operations for complete laceration through the sphincter. Considerable experience in operating on cases of complete tear has convinced me that a certain percentage of sepsis, even with the most extraordinary precautions, is, in these cases, unavoidable. It should be remembered also that sepsis occurring after an operation for complete laceration may be a grave condition and is sometimes fatal. Fatal sepsis from an operation for complete tear usually eventuates in peritonitis. The operation should, therefore, be regarded as a major one, and not to be undertaken excepting under the most favorable conditions. Four of the septic perineal cases recorded here followed operations for large thinned-out rectoceles in fat, elderly women. The only practical method for curing this condition is to employ an extensive Emmet's operation by which it is necessary to quilt sutures into the denuded rectocele in order to draw it back into the vagina. I am convinced that the stitch abscesses which occurred in each one of these 4 cases were due to carrying the stitch too near the rectal mucous membrane, and thus exposing it to infection. It is probable that by greater care and skill the sepsis in these 4 cases might have been avoided.

SEPSIS IN ABDOMINAL WOUNDS.

The figures in the table relating to sepsis in abdominal wounds are less satisfactory than those relating to plastic wounds. The sepsis in these wounds is divided into two types, as has been mentioned above; first, the slight infection of a catgut knot, which results in a small sinus, until the knot is discharged or extracted, and secondly, where the wound to a greater or less extent becomes generally septic. The only abdominal wounds in the entire series which became generally septic were hernias, either abdominal or inguinal, the sepsis in all the other wounds being of the first type, namely, infection of a catgut knot. In operations for abdominal hernia, I am accustomed to do a very extensive operation which entails a long wound that is exposed for a considerable length of time on account of the difficulty of

[1] Surg., Gynec. and Obstet., August, 1910

the operation. Most of the operations for ventral hernia are done on patients who have a large amount of abdominal fat. These factors, together with the necessity of dissecting away the fat extensively from the aponeurosis, make operations for ventral hernia peculiarly liable to sepsis. In these cases I have been able to reduce the percentage of infection by draining the dead space caused by the dissection of the fat from the fascia through stab wounds, one on each side of the lower end of the main wound. Penrose drainage tubes are used and can be placed in such a way as to be drawn out thirty-six to forty-eight hours after the operation without disturbing the dressing. It is most important to leave the skin wound absolutely dry before closing. What has been said about extensive abdominal hernia wounds applies also to the wounds of radical breast operations where a large wound area is exposed for a considerable length of time with much dissection of fat, and leaving of dead spaces. Nearly all of the septic cases recorded in the table occurred before I had adopted an effective method of draining the whole wound by means of the Penrose tubes. The necrosis of the angle of a skin flap due to plastic devices for covering in a widely dissected area is not a serious complication, leaving as it does only a small granulating space, which readily heals over.

The infection of buried catgut knots has continued throughout the series despite all efforts to prevent it. The trouble cannot be laid to the catgut, as all the catgut used was tested bacteriologically in the Free Hospital laboratory before being used and was invariably found to be sterile. From a study of the wounds of all the hospital cases for several years it has been noticeable that catgut knot infection is much more likely to occur in wounds where the edges are carelessly approximated, so that one overlaps the other. This doubtless accounts for the fact that in performing the same class of cases one surgeon may have more wound sepsis than another. In order to test this observation a change was made in the present series in the method of closing the skin. In about one third of the cases the skin was closed with interrupted silkworm gut sutures. The rest were closed by a few deeply placed silkworm gut sutures and a running No. 00 chromicized catgut stitch. The latter method secures a much better approximation of the wound edges, and shows a considerably lower percentage of catgut infection, though it has not entirely prevented its occurrence.

In common with other surgeons I note that wound infection is much more common in public hospital work than in private practice, where it is almost *nil*. This cannot be due to infection from other septic cases. At the Free Hospital the number of acute septic cases operated on is no greater than at a private hospital. Moreover, in our public hospitals, all the conditions for systematic avoidance of sepsis are superior to those found at the average private hospital. One is, therefore, driven to the conclusion that the difference is largely due to the personal equation of the patient, and that the person whose skin is habitually clean is far less likely to incur wound sepsis. This is a most important fact and establishes the principle that the preparation of public hospital cases must be much more rigorous than that employed for private cases. The technic which I am about to describe as being employed in the series of cases here reported will doubtless seem to many laborious and unnecessary. In the plastic cases the painstaking preparation, though requiring much attention on the part of the nurses, and some inconvenience on the part of the patient, seems to be thoroughly justified by the results. Out of 611 patients who received plastic operations, only 13 had any form of sepsis. In all these cases the sepsis was slight.

PREPARATION OF PLASTIC CASES FOR OPERATION.

Twenty-four hours before operation the patient is given magnesium sulphate, ℥ii. The external genitals are then shaved well up to the abdomen over the flanks and around the anus. A high soap suds enema with ℥i of turpentine is given. Successive vaginal douches are then given, first of soap suds, then plain water, then of bichloride 1–5,000, after which the area shaved is scrubbed with green soap on gauze. A bichloride pad soaked in 1–5,000 corrosive is applied and reapplied fresh every time the patient urinates. Early in the morning of the operation repeated enemas are given until the bowel is thoroughly empty, and the water runs clear. This is followed by a plain water and then a bichloride 1–5,000 vaginal douche. A fresh pad is applied and left until the patient is taken to the operating room. In the operating room after the patient is etherized she receives another scrubbing with gauze of the vagina and external genitals and all the parts then rinsed with sterile water. After a preparation of this kind an involuntary movement of the bowels during operation practically never happens. The care of the patient after operation is also of great importance for the avoidance of sepsis. Two douches, one of bichloride 1–5,000, and one of sterile water, are given daily until after the patient leaves the hospital. Perineal stitches are rinsed with sterile water under aseptic precautions after each urination and defecation. External perineal stitches are removed beginning on the fifth or sixth day, those being removed first which have a tendency to cut in or cause reddening of the skin. All the stitches are out on the ninth day, when the patients are allowed to sit up.

PREPARATION FOR LAPAROTOMIES.

In regard to skin preparation for laparotomies, there is a considerable divergence of opinion among surgeons, the tendency of the present day being more and more to regard the old-fashioned elaborate preparations as unnecessary. The methods used uniformly in the series here presented have been distinctly of the old-fashioned type, but have been adhered to from a conviction that the results so far as wound sepsis is concerned compare favorably with those in other public

hospitals where the more complicated methods of preparation have been given up. The abdomen is shaved and scrubbed twenty-four hours before operation, a green soap poultice being left on for six hours after each time. The abdomen is rinsed with sterile water and 70% alcohol, and a bichloride dressing is left on until the following morning, when the abdomen is again rinsed off with sterile water and alcohol and a fresh dressing applied. In the operating room the abdomen is treated with permanganate and oxalic, sterile water, and 70% alcohol. The use of permanganate and oxalic has been almost universally abandoned in other hospitals. I am still strongly in favor of its use, especially in public hospital practice, my convictions being formed after repeated bacteriological examinations of surgeons' and assistants' hands prepared by this method. The bacteriological results from the permanganate, oxalic and alcohol preparation are incomparably better than those from any other method tried, while the absence of injury to the skin and nails of the surgeon's hands is of itself, as compared with other methods, sufficient to recommend it. Rubber gloves are put on in a 1–10,000 bichloride solution.

The technic thus described was used in all the laparotomy cases, the number of which amounted to 574. As 28 of these became septic to a greater or less extent, it will thus be seen that the occurrence of sepsis was a little over twice that of the plastic cases. Considering the fact, too, that in the plastic cases, taking all the operations into account, there were nearly three times as many wounds, the percentage of sepsis in the laparotomy cases is still greater by comparison. As equal care was taken in the technic of both classes of cases, the results show that abdominal incisions are much more susceptible to superficial infection than are plastic wounds.

In order to compare the results of the technic of the present series of cases with other well accepted methods, I am now carrying out a series of cases in which the abdomen is prepared with the tincture of iodine. This method has apparently been extremely successful. A report of the results of this method will be made at a later date.

THE COMPARATIVE HISTOLOGY OF FEMORAL BONES.

BY J. S. FOOTE, M.D., CREIGHTON MEDICAL COLLEGE, OMAHA, NEB.

It is interesting to notice the diversity of structure present in the femurs of various animals. We have been led to think that bone is bone, that long bones, and especially similar bones wherever they occur, have the same structure because they are used for the same purposes. This is not true. Microscopical examinations of entire sections of thirty femurs of as many different animals show that the structures and their arrangements are not at all the same. They vary in different animals, and even in the walls of a bone of any one animal. The anterior wall is unlike the posterior; the outer wall unlike the inner. Nor are the linear portions of a bone the same. If a long bone, like the femur, is divided into thirds, each third is found to differ from another third. Therefore a correct knowledge of the histology of bone cannot be obtained from prepared sections of small pieces sawed from the walls of bones. Entire cross-sections must be made in each case. Furthermore, a drawing and description of one long bone will not answer for another.

In a general way femurs answer a common purpose, but in specific ways they differ considerably. The various habits of animals, the complex, muscular stresses to which their femurs are exposed, and the variations in position relative to the bodies which they support, demand corresponding structural arrangements peculiar to the animals possessing them. Thus the femurs of swimmers, flyers, scratchers, climbers, crawlers, runners and jumpers differ from each other very decidedly. Bone exhibits a very ready structural response to functional demands.

We are accustomed to one type of bone, viz., the Haversian system type. It is the familiar type described and plated in books. It is human and will not answer as a formula of the general bone structure of animals. In most cases a small piece of a long human bone is described. In some instances entire cross-sections of small bones, as the fibula, radius, metatarsal or metacarpal, are given. This type, in its pure form, appears to be peculiar to man, as none of the other femurs examined show it. The completely developed Haversian system evidently belongs to the higher animals and exhibits evolutionary forms.

Entire cross-sections of the femurs of the following thirty animals have been examined as they were received. They were not selected.

Frog, normal and fractured; snapping turtle, domestic turkey, wild turkey, wild goose, mallard duck, crow, domestic chicken, man, ox, prairie dog, peahen, large horned owl, woodchuck, dog, rabbit, sheep, pig, cat, skunk, mink; raccoon and os penis of same; muskrat, opossum, wolf (timber), goat, alligator, rat, wild cat, small gray fox.

All sections are taken from the middle of the shafts, ground to proper thinness, mounted in hard balsam and examined with the same objectives, oculars and tube lengths of a Zeiss microscope. Drawings are then made for the purpose of comparison and are intended to show the developments and arrangements of the lamellæ, laminæ, lacunæ and Haversian systems rather than their exact number.

The following general outline is followed in all examinations:

1. Antero-posterior diameter of the bone.
2. Lateral diameter of bone.
3. Antero-posterior diameter of medullary canal. (To show variations in shape and thickness of walls.)
4. Lateral diameter of medullary canal.
5. Medullary canal full or empty.
6. Trabeculæ of bone — present or absent.
7. Cancellous bone — present or absent.
8. Compact bone — extent of.
9. Hardness or density.
10. External circumferential lamellæ.
11. Development and arrangement of central

Haversian systems. (Haversian system type of structure.)

12. Internal circumferential lamellæ.

13. Laminæ — position of — concentric or oblique.

14. Lacunæ — character of — long and narrow or oval or round.

15. Canaliculi — character of.

16. Type of structure — lamellar — laminar or Haversian system.

Although the number of femurs is not yet large, it is large enough to reveal three types of bone formation — the lamellar, laminar and Haversian system.

1. The lamellar type is the simplest and is composed of several lamellæ of bone concentrically arranged around the medullary canal. Example, femur of frog.

2. The laminar type is more complex and is composed of several laminæ of bone concentrically arranged around the medullary canal. Each lamina consists of several lamellæ and is separated from adjacent laminæ by inter-laminar, concentric canals. Best example may be seen in the pig. Earlier forms — turkeys, peahen.

3. The Haversian system type is the most complex form and is composed of Haversian systems generally running parallel with the external and internal surfaces of the walls of the bone. The systems may be large or small, regular or irregular in shape, united by short lamellæ or laminæ of bone and enclosed or not enclosed by external and internal circumferential lamellæ. Best example, man. Other forms (but modified) may be seen in the sheep, dog, woodchuck, ox, wolf, goat, fox and rabbit.

The femurs of other animals are various combinations of these three types in different degrees of development and arranged according to the stress requirements of each. The structural units of the three types may be present in the femurs of many animals, but their developments, positions and proportions vary greatly in all. The types apparently appeared in the order given above. The lamellar, — frog, — laminar, — turkey, — family, and pure Haversian system in man.

The lamellar and laminar types characterize the larger number of femurs and are always well developed. This would be expected if they were the first to appear. Even in those femurs having very incomplete Haversian systems, the lamellæ and laminæ are completely formed.

A study of these bones shows a great diversity of structure and arrangement, wide differences in shape, thickness and hardness of walls and character of contents of the medullary canals. Some femurs are practically round, as those of the frog, turtle, crow, domestic chicken, skunk, owl, prairie dog. In some femurs the antero-posterior diameters are longest, as in the dog, pig, timber wolf, ox, wild cat, wild goose. In some the lateral diameters are longest, as in the domestic and wild turkeys, mallard duck, peahen, woodchuck, rabbit, sheep, cat, raccoon, mink, musk rat, opossum, man, goat, alligator, rat, fox. The largest number of femurs have the long, lateral diameters.

The walls vary in thickness. The peahen has the thinnest (and hardest) walls in proportion to the diameter of the bone, and the turtle the thickest.

The femurs of the turtle, alligator, peahen, owl, sheep, wild cat, goat, ox, pig, man are hard; of the wild goose, mallard duck, domestic chicken, dog, skunk, raccoon, mink and wolf are medium; of the frog, turkey, crow, prairie dog, woodchuck, rabbit, musk rat, opossum, fox, are soft. The degree of hardness is estimated by the grinding process in the preparation of sections. The contents of the medullary canals vary. The canals are empty in the frog, mallard duck, peahen, *musk rat*, *prairie dog*, and full in the turtle, domestic and *wild turkey*, *wild goose*, *crow*, *owl*, woodchuck, dog, rabbit, sheep, pig, cat, skunk, raccoon, mink, opossum, wolf, ox, man, goat, alligator, rat, fox, wild cat. That is, most canals are full. Some mammals are empty — musk rat and prairie dog — and some birds have full canals — wild goose, crow, owl, wild turkey. Two femurs have medullary trabeculæ of bone — peahen and musk rat; three have circummedullary cancellous bone — turtle, man and alligator. The external circumferential lamellæ are best developed and most prominent in the frog, cat, skunk, mink, raccoon, prairie dog, opossum, rat, wild cat.

The internal circumferential lamellæ are best developed and most prominent in the owl, opossum, musk rat.

The central complete Haversian systems are best developed in man, sheep, dog, woodchuck, ox, wolf, goat, fox, rabbit. They are undeveloped in the turtle, alligator, owl, wild goose, domestic chicken, turkeys, crow. Laminæ are best developed in the turkey, pig, peahen. They are absent in the chicken, skunk, mink, opossum. They are obliquely arranged in the rabbit and sheep.

The posterior ridges have the best developed Haversian systems. Nearly all femurs have two forms of lacunæ — long, narrow and oval, or round; and two forms of canaliculi — long, branching and bushy. Seven femurs are incompletely developed, that is, have incomplete Haversian systems, — turtle, alligator, owl, wild goose, mallard duck, chicken, crow. One is fully developed and of the Haversian system type — man. Eight are completely developed, but of a mixed type, that is, they have completely formed, lamellæ, laminæ and Haversian systems arranged in peculiar ways — sheep, dog, woodchuck, ox, wolf, rabbit, goat, fox. Four are laminar; ten lamellar.

Arranging the thirty femurs according to their types and structures, they fall into the groups as shown in table on next page.

It is rather unexpected that the femurs of these animals should fall into these classes. It may be noticed that man stands alone. Summary: Femurs differ in shape. Some birds of flight have full medullary canals, some poor flyers

Lamellar type.	Laminar type.	Incomplete mixed type.	Pure Haversian system type.	Complete mixed type.
Frog, cat, skunk, mink, raccoon, musk rat, prairie dog, opossum, rat, wild cat.	Domestic and wild turkeys, pig, peahen.	Turtle, alligator, owl, wild goose, domestic, chicken, crow.	Man. (The type usually drawn and described.)	Sheep, dog, woodchuck, ox, wolf, goat fox, rabbit.

have empty canals, some mammals have empty canals. Some femurs are nearly solid, some have extremely thin walls, some have medullary trabeculæ of bone, most have none. Some bones are hard, some medium, some soft. Some have circummedullary cancellous bone; most have none. Some have wide external circumferential lamellæ; some, narrow. Some have wide internal circumferential lamellæ; some, narrow. Some have concentric laminæ; some, oblique, and some have none. Some have complete Haversian systems; some, incomplete. Some have thick, central rings of Haversian systems; some, crescents, and some, alternating rings of systems and laminæ. Some show the lamellar type; some, the laminar, and some, the Haversian system. No two are alike excepting those of the same species. There is no femur like the human. The particular femur examined differs from the usual description in that it shows the external circumferential lamellæ very poorly developed and present only at scattered intervals around the periosteal border of the bone. The central ring of Haversian systems reaches the surface for the most part, and occasionally a half system forms the outer boundary of the section.

There is, perhaps, no other tissue of the animal kingdom which indicates the species of animal to which it belongs as clearly as bone. Epithelium, muscle, nerve and other varieties of connective tissue cannot be easily distinguished as peculiar to or characteristic of any animal. Femurs may be grouped by their microscopic structures, and these are sufficiently constant to form some sort of a classification. Bone of repair is cancellous. One of the femurs of the frog had been fractured in the middle of the shaft; the two fragments — proximal and distal — had slipped by each other, and new bone of repair had formed around them. There were cell outbursts from the medullary canal through the walls of the proximal fragment which appeared to initiate the reparative process. The new bone of repair was cancellous bone, although there was none in the femur at the line of fracture. In places the meshes of the cancellous bone had been reduced in diameter by the formation of lamellæ around their walls, forming Haversian systems which were also absent in the femurs.

In the femur of the pig the inter-laminar canals widen at intervals by circular dilatations, around which two or three lamellæ are bent, forming small Haversian systems. These are two methods of system formation.

At the present time it is not possible to account for the varying bone structures on the basis of diversified function alone. A general biological law operating in harmony with a changing environment and establishing the type of the genus is essential.

For example, the femurs of the pig and turkey resemble each other closely. The os penis of the raccoon resembles the femur of that animal. The turtle has four laminæ alternating with three rings of incomplete Haversian systems.

The turkeys have fifteen to twenty concentric laminæ interrupted in the posterior and anterior walls by Haversian systems.

The wild goose has from four to ten external and internal lamellæ, anterior and posterior incomplete Haversian systems; internal laminæ and external Haversian systems in the inner wall.

The crow has six to eight external and two or three internal lamellæ with a wide central ring of Haversian systems.

The peahen has a concentric network of laminæ around the medullary canal and a network of trabeculæ extending from one wall of the canal to the opposite.

The owl has three to nine external and thirteen to twenty internal lamellæ — six laminæ in the outer wall and a central ring of incomplete Haversian systems.

The woodchuck has two external laminæ, two internal laminæ and a central heavy ring of irregularly shaped Haversian systems.

The dog has an outer wall of Haversian systems and an inner wall of Haversian systems alternating with laminæ.

The rabbit has five to eight oblique laminæ merging into concentric oblique Haversian systems and lamellæ.

The sheep has six external lamellæ widening into twenty laminæ, two internal laminæ and a central crescent of Haversian systems.

The pig has seventeen to thirty-five concentric laminæ interrupted in the posterior wall by Haversian systems.

The cat has twenty-three to forty-five external lamellæ, two to six internal laminæ and a central ring of complete Haversian systems.

The skunk has fourteen to seventeen external lamellæ, six to eight internal lamellæ and an irregular ring of Haversian systems.

The raccoon has fourteen to fifty external lamellæ, two internal to one half of the thickness of the wall of oblique laminæ and an irregular ring of Haversian systems.

The mink has fifty to sixty external lamellæ, twelve to twenty-five internal lamellæ and an irregular crescent of Haversian systems.

The muskrat has a few external lamellæ at intervals, nearly the whole of the wall of undulating internal lamellæ enclosing solid cylinders of bone, a few incomplete Haversian systems and a transverse network of laminæ in the inner wall.

The opossum has two wide rings of external lamellæ, a wide ring of internal lamellæ (two

thirds of the wall) and a crescent of very incomplete Haversian systems.

The wolf has sixteen to twenty-one external lamellæ separating into four laminæ, six internal laminæ in the anterior wall, thick crescent of Haversian systems, and well-developed laminæ in the inner wall.

The ox has three wide concentric rings composed of irregularly shaped Haversian systems arranged in different directions, and enclosed by a few external and internal lamellæ.

Man has a few short external lamellæ at intervals, a wide central ring of Haversian systems and internal lamellæ arranged in cancellous bone.

The prairie dog has eight to fifteen external, six to twenty-five internal lamellæ and a narrow central ring of Haversian systems.

The goat has six to sixteen external, four to fifteen internal lamellæ, two or three laminæ and two rings of Haversian systems.

The alligator has no external lamellæ, three or four internal, four rings of incomplete Haversian systems alternating with four concentric laminæ.

The rat has six to ten external lamellæ, a few incomplete internal laminæ and a central ring of incomplete Haversian systems.

The fox has twenty to thirty external lamellæ, a heavy ring of internal laminæ and a central crescent of Haversian systems.

The wild cat has a wide ring of external lamellæ (two thirds of the width of the wall), three to thirty internal lamellæ and a crescent of Haversian systems.

It does not appear just what habits or conditions of environment call for lamellar type, laminar or Haversian system type of structure. Hardly any two animals are farther apart — apparently — than the pig and the turkey, and yet they have a common structure.

Looking over the femurs examined, the pure Haversian system type is shown in the smallest number of animals, the laminar in the next, while the lamellar comprises the largest number. Perhaps — in some cases — the principle of reversion has been introduced. Generally we are inclined to think of the Haversian system type as the one best adapted to support weight, but this does not work out in the pig.

The bones, furthermore, vary greatly in hardness, in contents, in relative thickness of walls and in shape. The study suggests a possible relation of pathological bone to their changeable factors. Deformities, changes in nutrition and growth may be governed by a failure of a bone to conform to the pure type.

It is the intention to continue the study, as it promises to widen the field of bone histology and possibly account for some of the individual variations in human femurs which are responsible for bone diseases.

The writer would be very glad to receive fresh femur of animals not mentioned in the list given above, and would also be glad to send, after Sept. 1, sawed rings of the femurs examined to any one who may wish to prepare them for study.

Medical Progress.

PROGRESS IN THE THEORY AND PRACTICE OF MEDICINE. GASTRIC AND DUODENAL ULCER.

BY FRANCIS W. PALFREY, M.D., BOSTON.

In recent years the study of gastric and duodenal ulcer has attracted much attention both from medical and from surgical investigators. To abdominal surgeons is largely due the credit for the inception of recent advances in these subjects, by observations possible only at operation which have called for a revision of our previous beliefs. These observations of surgeons have in turn stimulated the interest of physicians, and have led to renewed efforts on their part to explain the occurrence, and to perfect medical methods of treatment, of these conditions. The growing movement for experimental research has further shown its influence in investigations attempting to throw light upon the many unexplained points and disputed questions by studies upon animals. Much still remains in doubt. In fact, the pathological physiology of ulcers of the stomach and duodenum is still without conclusive explanations. Yet so much has been written of late in reports of careful research, both experimental and clinical, bearing upon the pathogenesis, recognition and management of cases of gastric and of duodenal ulcer, that a brief review of these reports seems desirable.

ETIOLOGY.

Round ulcer of the stomach was first described as a clinical entity by Cruveilhier in 1836. Similar ulcers have since then been known to occur in the duodenum, but until recently duodenal ulcer was supposed to be relatively rare and was not given independent consideration. But from the findings of Moynihan,[1] of the Mayos[2] and their associates, of Codman[3] and of other surgeons, it has been established that duodenal ulcer is not rare, but, on the contrary, comprises the majority of all chronic ulcers of the upper digestive tract. Ewald,[4] Musser[5] and Hoover[6] dispute this, but the surgical evidence seems incontestable. Furthermore, it is shown that duodenal ulcers give sufficiently definite symptomatology and clinical course to warrant their separation from gastric ulcers into a class of their own. Thus, in discussing the etiology and also the diagnosis, prognosis and treatment of so-called peptic ulcers, while certain considerations apply equally to all such ulcers, the distinction between the two types, the gastric and the duodenal, must be borne in mind and the differences between the two are to be noted.

The pathogenesis of these ulcers has been the subject of much study in which the work of recent years has shown no abatement. Self-digestion has long been believed to play a part, but it has been amply shown that self-digestion cannot be regarded as more than a contributing cause since the mucosa of the normal living stomach and of

the duodenum is immune to the digestive action of the gastric juice.[7] Some cause must be found to explain the failure of this normal immunity before ulceration by self-digestion can occur. This has been the object of recent experimental work, throwing a certain amount of light upon the plausibility of the various theories both old and new that have been suggested. The chief possibilities considered as prime factors in the etiology of gastric ulcer are as follows: (1) Some interference with the circulation of a portion of the stomach or duodenum; (2) some disturbance of innervation; (3) a local inflammation or manifestation of infection; (4) a secretory or motor abnormality of function; (5) a toxic or other influence from the blood.

Able discussions of the present state of our knowledge on this subject have recently been published by Mathieu and Moutier,[8] by Litthauer [9] and by Longcope.[10]

The theory of a circulatory abnormality, either arterial or venous, as cause of a local failure of the immunity of the stomach against self-digestion, first suggested by Virchow in 1853, and from then until now always in question, supported most notably by the work of Von Recklinghausen and of Cohnheim, has of late been investigated further by Fibich,[11] by Clairmont,[12] by Litthauer,[9] by Payr [13] and indirectly by Braun.[14] The first three of these investigators have dealt with the arterial supply. Fibich [11] reports that he was regularly able to produce in dogs an ulcer of the stomach which did not tend to spontaneous healing by ligation of smaller arteries of the stomach followed by excision of mucosa and cauterization with acid in the area which these arteries supplied. These ulcers he produced in order to test the effect upon their healing of gastro-enterostomy. Gastro-enterostomy in these experiments appears to have had a markedly beneficial effect. But this work of Fibich has been called in question by Clairmont,[12] who repeated the procedure of Fibich and found that the ulcers produced in his experiments differed essentially from clinical gastric ulcer in possessing a strong tendency to rapid spontaneous healing, and that gastro-enterostomy had no effect in accelerating the healing process. Litthauer [9] also repeated Fibich's experiments and also failed to confirm the results. Braun,[14] in investigating the safety of ligating arteries of the stomach to check hemorrhage, found that in dogs extensive ligations failed to produce necrosis. Litthauer [9] also found that a third of the stomach could be deprived by ligation of its afferent vessels without death of tissue. In other experiments, however, with extensive ligation of arteries until the stomach wall became livid, followed by excision and cauterization of mucous membrane, followed by the daily administration by the stomach tube of .37% HC solution, Litthauer found that chronic ulcers were produced in about a third of the animals so treated. These experiments taken together seem to show, as Litthauer concludes, that no certain method is yet known to produce chronic ulcers in dogs; these results, therefore, fail to support by analogy the arterial theory as a sole cause of gastric ulcer in man. Yet the rôle of interference with arterial circulation in connection with some instances of gastric and duodenal ulcer in man cannot be thus excluded. Sclerosis of arteries in the neighborhood of ulcers has been so frequently observed (Longcope,[10] Mayo,[3] Bunday [15]) as to establish strong suspicion that it may be still of etiological importance.

With regard to venous circulation, the work of Payr [13] is worthy of note. This work was undertaken in part to investigate the possibility of damage to the stomach by embolism or thrombosis consequent upon operation upon abdominal organs other than the stomach. Damaging of the veins of the omentum or mesentery by freezing or by hot solution, also injections of dermatol, of gelatine, of oil and of other substances into these veins, resulted in 50% of the experiments in lesions of the stomach, — hyperemia, hemorrhagic necrosis of mucous membrane, hemorrhagic erosions and ulcers. These lesions in certain instances contained the substances injected into distant veins, showing their embolic nature. Payr further demonstrated a possible mechanism for this retrograde embolism by tying the united trunk, draining two veins of the portal system, to simulate direct embolism or thrombosis, and showing that in consequence of obstruction of the main trunk the direction of the current in one of the branches became reversed.

Payr believes that in some instances digestive symptoms following abdominal operations are due to this process. His article suggests the question whether ulcers of the stomach which have been reported in connection with trauma,[16] with epigastric hernia,[17] with wounds of the urinary bladder [18] and with appendicitis [19] may not be produced by this mechanism.

The possible rôle of disorders of nerve supply was suggested by Stockton in 1892, and reiterated in a recent article,[20] suggesting an analogy between gastric ulcer and the perforating ulcer of the foot in tabes dorsalis and herpes zoster. This possibility has recently received support from the experimental evidence of Ophuls,[21] of Zironi [22] and of Van Ijzeren,[23] confirming the previous observation of Della Vedova [24] that section of nerves leading to the stomach was followed in a half of the animals (chiefly rabbits) so treated by necroses, hemorrhages and ulcers. Donati [25] and Lilla,[26] however, failed to obtain these results.

The theory that gastric ulcer may be due to an infective or irritative gastritis has long been discussed. The possible rôle of simple gastritis cannot be established or excluded, since, although some inflammatory changes occur in chronic ulcer, this has usually been regarded as secondary to the ulcer rather than primary. That acute ulcerations of the stomach may occur in a variety of infectious diseases is well recognized. But whether chronic ulcer may be caused remains uncertain. Of recent publications bearing upon this question may be mentioned that of Mahnert,[19] who advanced the theory that preceding appendicular infections may be an etiological factor,

finding unquestionable chronic appendicitis in 23 out of 36 cases of proved gastric ulcer. But as Mahnert himself points out, this reasoning may also support Payr's suggestion rather than that of infection alone, since the appendicular inflammation might well give rise to retrograde venous embolism of the stomach. Many investigators have produced ulcerations of the stomach by injection of a variety of bacteria, but these ulcerations have been acute rather than chronic. Considerable attention has been attracted by the results published by Turck,[27] who claimed to have produced gastric or duodenal ulcers in all of a number of dogs previously kept confined in poor environment and later fed daily with cultures of Bacillus coli communis. His experiments, however, have been repeated by Bauer[28] with entirely negative results.

Kodon[29] has recently advocated the view that round ulcer is to be regarded as a tuberculide, reporting in 53 cases of gastric ulcer the presence of marked tuberculosis in 49 and of tuberculides in 5. He compares gastric ulcer with lupus. His evidence, however, does not seem of sufficient weight to justify serious consideration of so radical a suggestion.

In this connection may be mentioned a form of infection which, while not producing true peptic ulcer, still, as is emphasized by Hoover,[6] may cause a clinical picture indistinguishable from it, namely, syphilis. Curtis[30] and Kohn[31] have each reported a case of syphilis of the stomach with pathological examination. Hoover reports 5 cases simulating gastric ulcer which promptly recovered under antisyphilitic treatment.

Hypersecretion, first demonstrated by Riegel in 1886, in cases of gastric ulcer, has been generally held to be incapable in itself of producing gastric ulcer, yet in the experiments of Bolton[32] it is shown that artificially induced extreme hyperacidity in animals can produce gastric ulcer, and Weinland[33] has shown that excessive acidity can overcome the action of the protective antiferment to be mentioned later. Grandauer[34] has emphasized the close clinical relation between hypersecretion and ulcer. It is further possible that hypersecretion, to which is added the presence of a disorder of motor function, may be of greater effect. Frouin[35] reports that repeatedly and regularly, when he has fed to experimental animals with an isolated stomach pouch, food containing an excess of sodium chloride, and has left the pouch for a time without evacuation, the contents have become hemorrhagic, which he takes to be evidence of erosion or ulcer, whereas the contents of the pouch in similar animals fed with normal amounts of NaCl could be left in much longer and with greater distention of the pouch without showing any such abnormality. Moutier[36] also describes the frequent spontaneous occurrence of ulcers closely resembling the *ulcus rotundum* of Cruveilhéir in the isolated stomach pouch of dogs. In these animals at operation great care had been exercised to avoid interference with vessels or nerves. Codman,[37] dealing only with questions concerning the duodenum, has published an extremely suggestive clinical article attempting to establish a connection between duodenal ulcer and chronic constriction of the duodenum by the root of the mesentery, supposing this to cause an abnormally long period of contact between duodenum and the digestive fluids. At operation he observed such a condition, with recovery following the relief of the constriction, which was due apparently to an enteroptosis. In this connection may be mentioned Czernecki's[38] report of the occurrence of gastric ulcer in a mother and in her four adult offspring, all presenting marked visceral ptosis.

But aside from disturbances of long-recognized functions of secretion and of motility, other considerations have been brought to attention. Kauffmann,[39] supported by Aldor,[40] has attempted to show that a deficiency of gastric mucus is found in gastric ulcer and that the disease is due to lack of mucus as a protection against the action of the gastric juice. More attention has been attracted by application of the work of Weinland,[33] who demonstrated in extracts of gastric mucosa and of intestinal parasites which live in immunity to digestion an *anti-ferment* which has the power of inhibiting peptic digestion. Although this is disputed by Von Klug,[41] Katzenstein,[7] Stockton[20] and others regard the deficiency of this antiferment as the essential factor in the production of ulcer by self-digestion, Stockton[20] suggesting that this deficiency is in turn due to abnormality in innervation.

The last theory, that gastric ulcer is due primarily to the presence of toxic or the absence of needful constituents in the blood or body fluids, originated long ago in the recognition of the frequent coexistence of ulcer with chlorosis and of the occurrence of acute ulcer in intoxications. The action of the toxic substances in producing experimental ulcers of the stomach has been studied recently by Rosenau and Anderson,[42] who demonstrated the production of lesions of the stomach in guinea pigs injected with diphtheria toxin; by Gay and Southard,[43] who found gastric ulcers following the toxic injection in anaphylaxis experiments; and by Rehfuss,[44] who succeeded in producing ulcers of the stomach in 35 out of 41 animals by injection of various toxic agents. Beginning with the venom of the gila monster, Rehfuss was equally successful with pilocarpine, atropine, paraldehyde, phenol, chloroform and $MgCl_2$. He concludes that in severe intoxication by a great variety of agents ulcer may be produced. He further showed that when the stomach was injected with sodium bicarbonate in these experiments an ulcer was less likely to develop, appearing in but 6 out of 30 animals. This is taken as evidence that autodigestion is an essential part of the process. Litthauer[9] experimented with pyronin injections, aiming to test the effect of hemoglobinemia, but without striking results.

Of great interest is the work of Bolton,[32] who was able to produce ulcers of the stomach by means of a gastrolytic serum. He prepared this serum from animals injected with emulsions of

stomach mucous membrane; the serum of these animals injected into other animals resulted in the formation of ulcers of the stomach. Like the ulcers in Rehfuss' experiments, these failed to occur if the acid of the gastric juice was neutralized. Hort,[45] basing his argument chiefly on Bolton's work, has propounded the theory that gastric ulcer and chlorosis are due primarily to a blood disease, the essence of which is the presence of a toxic substance exerting its action both upon the gastric mucosa and upon the blood corpuscles. His evidence, however, is far from sufficient.

In spite of all these data, however, we are still far from a clear solution of the problem. Even at first sight such an array of conflicting evidence tends rather to confuse than to enlighten. Yet on closer consideration the conclusions reached by Mathieu and Moutier[8] seem highly plausible. It has been seen in the accounts of experimental work mentioned in the previous paragraphs that ulcerations of the stomach may result from interference with circulation, either arterial or venous, from interference with innervation, from infections, from extreme hyperacidity of contents, especially where the contents are long retained, from deficiency of normal protective influences (mucus or antiferment), and from a variety of toxic influences. In several at least of these sets of experiments the co-operation of acid gastric juice was essential to the production of ulceration. A co-existence of ulcer with chlorosis and debility on the one hand and with an overwrought nervous system is mentioned by various authors. Mathieu and Moutier believe that the best solution of the problem lies in the belief that the ulcerations in the first place may be due to a variety of causes, — some to one, some to others, — but that when once an ulceration is produced by any cause in a portion of the alimentary tract bathed for prolonged periods by active digestive fluids, the combined influences of autodigestion, of secondary gastritis with interstitial lymphangitis, and a lowered state of bodily resistance, may convert an ulceration of any type into the typical round ulcer of Cruveilhier.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

Meeting at Washington, D. C., May 3, 4, 5, 1910.

[Continued from No. 15, p. 588.]

REPORT OF A CASE OF HEPATICO-DUODENAL ANASTOMOSIS.

George Emerson Brewer, M.D., of New York, N. Y.: The patient was admitted to the Roosevelt Hospital suffering from acute cholecystitis. Following a cholecystectomy there occurred extensive sloughing of the wound, which was followed by a complete biliary fistula. At the end of seventy-five days, as no bile was passing into the bowel, the abdomen was reopened and the fistula followed down to the common hepatic duct. As no trace of a common duct could be found even after reflecting the duodenum and exposing the head of the pancreas, it was assumed that it had been destroyed by the suppurating process which followed the primary operation. A rubber drainage tube three inches in length was introduced into the hepatic duct and also through the duodenum by a stab wound at its upper border, and was secured in these two situations by two purse-string sutures. A mass of omentum was then wrapped around the tube, extending well beyond its introduction in the hepatic duct and duodenum with a view to create a new common duct after the manner suggested by Sullivan. The abdominal wound was closed, a small cigarette drain being allowed to remain at its upper angle. From that time no bile appeared in the wound. The bowels moved on the third day as the result of an enema, and the stools contained an abundance of bile. The reconstructed duct continued to functionate until after the man's discharge from the hospital some four or five weeks after the last operation. Since then he has had two or three attacks of fever associated with jaundice, which would disappear in two or three days. At the present time he is still jaundiced, although some bile is present in the stools.

Dr. Brewer asked the advice of the members of the Association as to further treatment in case the newly constructed duct became totally occluded.

DISCUSSION.

Dr. Alexander H. Ferguson, of Chicago: Since the observation that if all the bile is directed into the hepatic flexure of the large bowel the patient does not suffer from the lack of bile (which observation I believe was first confirmed by Mayo Robson), I have followed this technic in at least half a dozen cases with extremely gratifying results.

DR. JOSEPH C. BLOODGOOD, of Baltimore: I would like to report an anastomosis of small intestine by opening the transverse colon as in posterior gastro-enterostomy, sewing a long loop of the small intestine through the transverse colon, and suturing it to the gall bladder.

RESECTION OF THE PANCREAS, WITH REPORT OF A CASE.

J. M. T. FINNEY, M.D., of Baltimore, Md.: The principal object of this communication is to record the successful removal of a primary solid tumor of the pancreas. The operation involved the resection of the entire middle portion of the gland, leaving only a small piece of the head and the tail respectively, and necessitating a reunion of these segments by suture. A search of the literature reveals records of but sixteen other undoubted cases in which the pancreas has been resected, either in whole or in part, for primary tumor of the gland.

A review was given of the recent advances of surgery of the pancreas due to experimental and clinical work. The difficulties of operating upon the pancreas were referred to and the best methods of avoiding and controlling the same. The best methods of dealing with pancreatic fistulæ were next taken up. The diagnosis of primary solid tumors of the pancreas is made usually by exclusion, and it is not always possible beforehand. Different routes for attacking pancreatic tumors were discussed and the various operations which had been suggested were described. These were so difficult and dangerous as to prevent their general use.

The statistics of the operation for primary tumor of the pancreas were given. Of the 17 cases, 12 occurred in females and 3 in males. Carcinoma occurred 10 times, sarcoma 4, fibro-adenoma 2, cystic adenoma once. Of the 17 cases, 9 recovered and 8 died. In 2 instances the pancreas has been reported as having been removed *in toto*. Three times the gland was completely divided into two parts, and the remaining portion sutured. All 3 cases recovered.

DISCUSSION.

DR. M. L. HARRIS, of Chicago: I would like to mention a case of a policeman shot by a 38 caliber bullet which entered just below the twelfth rib on the left side and was found just beneath the skin a little to the right of the median line between the eighth and ninth ribs. The track of the bullet from before backward was through the right lobe of the liver, the lesser curvature of the stomach, the middle of the pancreas, practically bisecting the organ, and the left kidney. The stomach was sewed up, then the pancreas, and as close an approximation of parts made as possible. Drainage front and back. Fistula resulted but closed in about three months and patient fully recovered.

DR. G. E. ARMSTRONG, of Montreal: With regard to the mobility of pancreatic tumors, I would like to mention a case in which there was a large pancreatic cyst which for a long time, because of its mobility, was considered to be a growth in the stomach.

DR. WILLY MEYER, of New York: I have had two cases in which the tail of the pancreas was tightly adherent to the existing tumor, and here I put a piece of chromicized gut around it and divided the distal end with the Paquelin cautery. Bost patients recovered.

DR. RUDOLPH MATAS, of New Orleans: I wish to report an additional case of unusual character, thrombosis of the splenic artery incidentally involving the pancreatic arterial supply, causing degeneration of the organ from the head to the tail, associated with multiple tumor formation in the spleen. The spleen and three quarters of the pancreas were removed and the patient recovered from the operation, dying about three years later from a slow fever.

CONGESTION OF THE LOWER LOBE OF THE RIGHT LUNG AN EARLY SYMPTOM IN APPENDICITIS.

JOHN B. ROBERTS, M.D., of Philadelphia, Pa.: The author suggested the possibility of a secondary congestion of the lower part of the right lung being found in a considerable number of cases of acute appendicitis. He spoke of this condition being a possible aid in the diagnosis of acute appendicitis when the symptoms of the latter were not yet very definite. A point was made that this observation did not refer to secondary pleuritis, and pulmonary involvement occurring in the late stages of appendicitis. Such inflammation from septic invasion secondary to advanced appendicitis was an entirely different process. The idea of the author evidently was that appendicitis, and perhaps other intra-abdominal inflammations, might cause atelectasis of the right lung, or a true congestion, because of the insufficient action of the diaphragm upon the right side. This spasm or immobility of the right side of the diaphragm he compared with the tonic spasm of the muscles overlying the appendix in the front of the abdominal wall. It was, however, also suggested that the engorgement of the base of the right lung in cases of appendicitis might be due to a simultaneous infection of both the appendix and the lung by the pneumococcus or other invading organism. The well-known fact that pneumonia is sometimes accompanied by pain and muscular rigidity in the right iliac fossa was mentioned, as was also the clinical observation that acute appendicitis may in its early stages give rise to pain in the right lower thoracic region. The early congestion of the right lung, which Dr. Roberts thinks he has found in the early or initiatory stages of appendicitis, might also occur from inflammation of the gall bladder or cellulitis around the upper pole of the kidney. The paper referred to somewhat similar observations by other writers, which seemed to at least partially confirm the correctness of the value of this new point in the diagnosis of appendicitis.

VACCINE THERAPY AS AN ADJUNCT TO SURGERY.

JOHN B. DEAVER, M.D.; JOHN C. DACOSTA, JR., M.D., and D. B. PFEIFFER, M.D., of Philadelphia, Pa.: There has been established at the German Hospital a special department of vaccine therapy. In addition to its well-known and satisfactory use in suppurative affections of the skin and other forms of minor chronic infection, this form of treatment has been used as an adjunct in the treatment of more severe surgical infective conditions.

Vaccines did not prove of service in 3 cases of streptococcic septicemia in which the treatment was begun late. Four cases of severe staphylococcic septicemia recovered, improvement in each case beginning with the initiation of the vaccine treatment. Eight cases of severe septic intoxication without demonstrated bacteremia were treated by drainage and vaccines. Two were *in extremis* when treatment was begun and died shortly afterwards. The remainder recovered. Five of the cases were streptococcic infections.

Improvement was also noted in a miscellaneous group of cases comprising persistent sinuses, cystitis, thrombosis, etc. Not all cases, however, gave a definite response. The dosage varied from 25,000,000 to 750,000,000. The sicker the patient and the less satisfactory the response, the smaller and less frequent should be the dose. Streptococcus also was used in smaller dosage than staphylococcus.

On the basis of these results the paper concludes:

Specific vaccine treatment in our hands has not

proved of benefit in the later stages of streptococcic septicemia.

Staphylococcic septicemia has been treated with most favorable results at all stages.

Septic intoxications without demonstrated blood invasion in a majority of the cases display general and local improvement under the use of vaccines if given early; the later the treatment, the less certain and satisfactory the result.

Localized and persistent suppurating lesions are sometimes markedly benefited by vaccines.

Surgical procedures for the relief of infectious conditions should be reinforced by vaccine treatment, which should be begun as early as is consistent with the case, and preferably by autogenous organisms.

No hospital can be considered fully equipped which is not prepared to supply this form of treatment in conjunction with established measures.

THERAPY BY BACTERINS AND TUBERCULINS IN MIXED SUPPURATIVE BONE AND JOINT DISEASE.

De Forest Willard, M.D., and B. A. Thomas, M.D., of Philadelphia, Pa.: The authors recount their experience of two years' duration in the treatment by bacterins and tuberculins of tuberculous bone and joint disease, complicated by mixed pyogenic infections. The feature of the treatment consists in the alternation of bacterin and tuberculin inoculations in the mixed suppurative type of the disease, as spinal caries, tuberculous hip-joint disease, etc. They do not contend that bacterin therapy is a "cure all," nor that when indications for surgical intervention exist, they can be disregarded and active immunization substituted. They wish, however, to emphasize the fact that the *accessory* employment of bacterin and tuberculin in certain cases stimulates the tissue cells of the organism to the production of specific antibodies to assist the bodily defenses in antagonizing and combating the given infections. On the other hand, the incompetent, inexperienced and careless use of these measures will not only fail to effect cure, but will inevitably lead to disaster and thrust a therapeutic measure of worth into disrepute. Bacterins, particularly tuberculin, are more potent agents for evil than for good, unless wisely administered. They are invaluable aids in competent hands, and when so employed these cases do better than those treated without bacterins; their detention in the hospital is shortened, and complications, if they occur, are fewer and less severe.

The authors present two definite clinical types of disease illustrated by charts, in which therapy by bacterins and tuberculins is recommended. The first type is represented by the case in which already at the time of operation a mixed infection of hematogenous or exogenous origin has been superimposed upon suppurative tuberculous caries. The second type is manifested in the evacuation and drainage of a "cold abscess," in which case almost invariably, after a lapse of fifteen to twenty days, the temperature suddenly rises and symptoms of a mixed infection ensue.

These types of disease are of a serious character, not those mild cases which would recover following simple incision and evacuation, nor those neglected ones of prolonged suppuration, characterized by bacteremia, grave sapremia and amyloid disease, but those with chronic localized processes, the treatment and prognosis of which have been greatly handicapped by the intervention of various pyogenic bacteria.

The authors have found that in the course of weeks the various pathogenic bacteria isolated from the suppuration vary, and for that reason they insist upon the employment of autogenous bacterins, the pus being cultured and recultured at least monthly. As soon as the patient's temperature falls to 100° or preferably lower, under the administration of bacterins, inoculations with tuberculins, either alone or alternating with bacterins for a time, are begun. They conclude, judging from the cases under their observation, that better results have attended the process of active immunization when, just as in tuberculin therapy pure and simple, the treatment has been commenced with relatively small bacterial inoculations, progressively increased to the therapeutic limit, rather than by recourse to large dosage, thereby in the former case establishing immunity, and in the latter avoiding anaphylaxis.

Studious observations of the clinical symptomology have always sufficed to control the treatment, the opsonic index proving not only impractical, but unreliable.

DISCUSSION.

Dr. J. M. T. Finney, of Baltimore: In regard to the use of vaccines in chronic infections of the bladder from the colon bacillus, I would mention a case in which, after every other method had failed, injections were followed by the most astonishing results, the bladder symptoms all practically disappearing.

Dr. Willis G. Macdonald, of Albany: I would like to call attention to the extreme importance of not giving too large a dose of vaccines, as I have found this regulation of the dosage very troublesome in those cases in my experience.

Surgeon-General Sternberg, of Washington: It is impossible to doubt that vaccine treatment is beneficial in a certain class of cases, but it is difficult to understand why it should be. You have a certain specific micro-organism in the blood in large numbers, producing toxic products, and why the introduction of a comparatively small number of the same micro-organisms under the skin should have such a potent effect in arresting the progress of the disease is to me inexplicable.

Dr. L. L. McArthur, of Chicago: I want to call attention to the tuberculin treatment in essential hemorrhage of the kidney. Treatment with the autogenous vaccine of the colon bacillus in several such cases has been productive of a cure, and I consider this a most beneficial treatment in this condition.

Dr. John B. Murphy, of Chicago: The essential hemorrhage of the kidney, the essential hemorrhage of the uterus occurring in girls under twenty with tuberculous histories, respond marvelously to proper dosage with tuberculin. Great assistance is rendered by this treatment in cases of bone tuberculosis. There is, however, no more treacherous and dangerous a drug than tuberculin if improperly given. As a stimulant, and as an aid to surgical tuberculosis, I know of nothing so good when the treatment is carefully administered.

Dr. Joseph C. Bloodgood, of Baltimore: I have had no experience in the vaccine treatment, but would like to suggest in regard to the essential hemorrhage of the kidney that a more simple serum be tried first. The professor of pathology at Tufts College has demonstrated the rapidity with which blood serum of all animals will check hemorrhage, so perhaps it is some antibody in the serum and not the organism that checks the hemorrhage when tuberculin is used in these cases.

Dr. Joseph A. Blake, of New York: I have been employing the vaccine treatment pretty persistently, and in chronic infections have found the autogenous vaccines of great benefit.

Dr. Arthur Dean Bevan, of Chicago: From my limited knowledge I would consider it too early at this time to arrive at any definite conclusions with regard to the value of this treatment. I have been particularly interested in the application of the vaccine treat-

ment to tuberculosis of the kidney and mixed infection of tuberculosis of the colon, and although I know of cases which under good management with this treatment have gone on to recovery, I also know of cases which without the vaccine treatment also recovered.

DR. FRANCIS B. HARRINGTON, of Boston: I have seen some cases in which autogenous vaccines have been of great benefit, and also some cases in which they were productive of great harm.

DR. HARRY M. SHERMAN, of San Francisco: We are using tuberculin more and more in the Children's Hospital. With regard to the vaccine treatment, we have had no success with the streptococcus infection.

DR. EMMET RIXFORD, of San Francisco: I would like to mention a case of tuberculous anal fistula, tuberculosis of the spinal cord and tuberculosis of the wrist which under treatment with tuberculin was completely restored to health. It has been two years since the treatment, there is now no sign of tuberculosis, and the patient has gained 40 lb. in weight.

DR. JAMES E. MOORE, of Minneapolis: I have been disappointed in the serums for the treatment of acute infections. In tubercular cases I have had better results. It is very essential that these treatments should be carried out only by those who know how to use them.

DR. CHARLES A. POWERS, of Denver: In chronic infections, especially the chronic staphylococcic infections, the autogenous vaccines have not given me the encouraging results which many others have obtained, and I, therefore, attribute this to faulty methods.

DR. CHARLES H. MAYO, of Rochester, Minn: In regard to the vaccine treatment, I would say that I have had very little experience with it, but I have had one case of colon infection of the bladder and kidney in which the autogenous vaccine has proved of benefit.

DR. JOHN B. DEAVER, of Philadelphia (in closing): The toxin treatment is most satisfactory if used judiciously. Like all good surgical measures, it must be instituted early to obtain the best result. The dosage is most important and should be carefully studied and regulated to the individual case.

DR. DE FOREST WILLARD, of Philadelphia (in closing): There are four things to remember in the use of tuberculin. First, tuberculin is a potent agent for evil as well as for good. It must be used carefully and in careful hands. Second, if a stock vaccine is used by incompetent men, the treatment will have disastrous results. Third, the dose must be exceedingly small, for the smaller the dose and the longer time consumed in the treatment, the more certain the beneficial results. Fourth, it is by no means a substitute for surgical procedures.

THE STUDY OF THE ETIOLOGY OF CANCER BASED ON CLINICAL STATISTICS.

ISAAC LEVIN, M.D., of New York, N. Y.: The investigations are based upon a clinical study of 4,000 cases of carcinoma and sarcoma collected from several large hospitals in the country, the analysis of which showed many results of interest. The greater frequency of the disease in women is due to the prevalence of cancer of the uterus and the female breast. The other organs become affected more frequently in men, which fact may be due only to the greater subjection of the latter sex to the different injurious influences of civilized life. Cancer, while considered to be a disease of an advanced age, appears, according to this investigation, to occur in many instances in people who have not yet reached middle age. Childbearing does not seem to have any direct connection to the causation of cancer. Another point of interest is the fact that American Indians rarely contract the disease. The data on the influence of occupation in the etiology of the disease were very defective and no conclusion could be derived from them. It is expected that with the co-operation of the profession better results will be obtained in this connection in the future work. The presence of a preceding local disease in the organ affected with cancer, while of certain importance, cannot be considered as the main etiological factor. Hereditary disposition does not seem to have an influence upon the causation of the disease sufficient to warrant the great dread of the lay public before this hereditary trait.

In conclusion, the statement may be made that while this investigation cannot claim to have reached any final result in the elucidation of the etiology of cancer, it appears evident that a local trauma or previous disease of the affected organ is of less importance in the causation of cancer than the increased vulnerability and lessened resistance of the organism caused by the ever-increasing strain of the modern life. This is certainly the only explanation that may be offered for the increasing frequency of the occurrence of cancer in civilized communities. That this increase is not only apparent is very evident from the mortality statistics of the United States in 1907, which shows a ratio of 73.1 deaths from cancer per 100,000 population, as compared with the ratio of 70.8 in 1906.

It is expected that this statistical cancer research, which is still being continued, may arouse the interest in the matter in the members of the profession, who are requested to fill out the schedules, which may be obtained on demand, and offered free examination of tumor tissue.

DISCUSSION.

DR. CHARLES A. POWERS, of Denver: I want to call attention to the formerly prevalent idea that youth was a bar to carcinoma. During the past year I have had no less than three patients under twenty-four years of age suffering from epithelioma.

ON THE SIMULATION OF NEOPLASMS BY INFLAMMATORY PROCESSES.

C. A. HAMANN, M.D., of Cleveland, Ohio: The resemblance, clinically, between certain inflammatory processes and tumors, leading to errors in diagnosis.

Chronic osteomyelitis and other forms of bone disease resulting in enlargement of bones; formative osteitis, as the result of various irritants, leading to the production of swellings which simulate neoplasms. Methods of differentiation. Myositis ossificans, circumscribed enlargements of muscles, myositis fibrosa.

Inflammatory thickening around foreign bodies in abdominal wall (" ligature and foreign body tumors "), inflammation of the omentum after ligation of portions of it.

Pseudo-neoplasms of stomach. Inflammatory pseudo-neoplasms of intestines; peri-appendicular swellings; diverticulitis, associated with the formation of connective tissue masses; tumors of the rectum and perirectal tissues, inflammatory in origin. So-called disappearing tumors are in many instances inflammatory pseudo-neoplasms.

Chronic mastitis in some of its various forms.

DISCUSSION.

DR. HARRY M. SHERMAN, of San Francisco: I would like to report an instance in which I through a mistaken diagnosis removed an inflammatory mass believing it to be sarcoma including the parotid gland. A radical operation was done, beginning with the clavicle, with removal of all the tissues up to and including the parotid gland, following the report on a section of the growth sent to the pathologist that it was

probably of sarcomatous origin. When the whole mass was sent to the laboratory for examination, however, it was proven to be an inflammatory mass in the center of which was a normal parotid gland. In the light, however, of no clinical symptoms of syphilis and a negative Wassermann, and a definite tumor mass, the evidence against syphilis in the diagnosis was enough to justify the operation for sarcoma.

A REVIEW OF ONE HUNDRED AND TWENTY RESECTIONS OF THE RECTUM FOR CANCER.

WILLIAM J. MAYO, M.D., of Rochester, Minn.:

Total number of resections of the rectum for cancer in St. Mary's Hospital from April 21, 1907, to Dec. 31, 1909,		120

Book Reviews.

Prophylaxis and Treatment of Syphilis. By GEORGE M. KATSAINOS, M.D. New York: The Phoenix Press. 1910.

This volume written in Greek is addressed primarily to Greeks resident in the United States, and is intended presumably for the laity rather than for the profession, since its purposes, as stated in the preface, are to teach the prophylaxis of syphilis, to convince syphilitics of the importance of perseverance in treatment, and to persuade them to abstain from marriage until their disease is no longer communicable. In accordance with this plan there are interesting popular chapters on the history, distribution and spread of syphilis, its natural phenomena, its etiology, and its modes of communication. The section on prophylaxis is the longest in the book. Apart from the matter of ethics, it may be questioned whether the suggestion of mechanical preventive measures against genital infection may not do positive harm by inspiring a false sense of security in their use. The instruction on the avoidance of extragenital infection, however, seems altogether desirable, and the chapters on the hygiene of the syphilitic and on syphilis and marriage contain much valuable dogma. In conclusion the "syphilitic's decalogue" sums up the rules and duties of the patient in admirably concrete, succinct and emphatic form.

The Diseases of Women: A Handbook for Students and Practitioners. By J. BLAND-SUTTON, F.R.C.S. Eng., Surgeon to the Middlesex Hospital, and Senior Surgeon to the Chelsea Hospital for Women; and ARTHUR E. GILES, M.D., B.Sc. Lond., F.R.C.S. Edin., Surgeon to the Chelsea Hospital for Women and Gynecologist to the Tottenham Hospital. Sixth edition, with 123 illustrations. New York: Rebman Company.

The sixth edition of this excellent small textbook comes to us with only eighteen pages more than the fifth edition published four years ago. In the latest volume there is a short chapter on "Fibrosis Uteri," summarizing the work of Bland-Sutton, Palmer Findley and Gardner and Goodall in this affection, and also a chapter on "Adenomyoma of the Uterus." Other new features are a short chapter on "The Vermiform Appendix as a Pelvic Organ" and one on "Injuries of the Ureters in the Course of Pelvic Operations and their Treatment," and an addition to the chapter on "Injuries of the Uterus," describing, in addition to lacerations of the cervix, gynecological injuries such as perforation during curetting, and obstetrical injuries, with their treatment.

There are several emendations to the text and new illustrations here and there, one of them in color. The book is well written, suitably illustrated, is small and easy to handle, and is not burdened with references. It is plain to see why it has proved acceptable to a large number of readers.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, OCTOBER 20, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

DR. CRILE'S ETHER ADDRESS.

THE sixty-fourth anniversary of Ether Day was appropriately observed last Saturday, Oct. 15, at the Massachusetts General Hospital. The principal speaker at the exercises was Dr. George W. Crile, of Cleveland, whose address will be printed in full in a later issue of the JOURNAL.

Dr. Crile showed not only excellent judgment but great courtesy to the hospital and to the medical profession of Boston in selecting this occasion to present the results of his valuable and scholarly research into certain problems connected with anesthesia. His investigations demonstrate by experimental evidence that so-called surgical shock represents the exhaustion of nerve-cells by discharges of energy which take place under the stimuli of operative trauma, even though general anesthesia prevent their conscious perception and motor manifestation. This exhaustion is shown by morphologic changes in the cells precisely similar to those produced by protracted muscular exertion. That such exhaustion may also be caused by emotion is demonstrated by the occurrence of the same morphologic changes in fear, which occasions discharge of nerve energy without motor phenomena. These observations Dr. Crile then correlates and explains on the basis of phylogenetic association, whereby the cumulative experience of individuals through countless ages of evolution has developed in the species not only the power of such automatic discharge of nerve energy in response to the deleterious stimuli of environment as shall tend best to preserve the individual from injury, but also the appropriate mechanism, the "nociceptors," by which such stimuli are received and transmitted. To prevent the exhaustion, the surgical shock, due to this unconscious discharge of nerve energy under the stimuli of operative trauma, as under the traumatic stimuli of the struggle for existence, it is necessary to block the afferent path of these nociceptors; and this, Dr. Crile has demonstrated experimentally, may be done by cocaine, the use of which prevents the stimuli from reaching the brain and causing there the responsive discharge of energy with its consequent morphologic cell changes representing exhaustion. Inhalation anesthesia, then, to use one of the many happy phrases with which Dr. Crile throughout illumined his exposition, "is only a veneer"; it obscures superficial consciousness of pain but does not penetrate deep enough to check the exhausting discharges of nerve energy which phylogenetic habit produces in the individual in response to "noci-associations" developed from experience of the traumatic stimuli of evolution. To the ideal surgical condition in which such exhaustion is prevented both by cocaine blocking and by the tactful immunization of fear in the patient, Dr. Crile applies the term "anoci-association." This condition, he believes, though not necessary in the majority of surgical procedures, is desirable and obtainable to a measurable degree in cases which for any reason are "poor surgical risks," and especially in the operative treatment of Graves' disease.

Dr. Crile's address, therefore, does not merely present a piece of laboratory research, but by luminous philosophic deduction rationalizes the data of that research and applies them to the solution of important practical problems in surgery. The last word on anesthesia was not spoken when the safety of ether as an anesthetic agent was successfully demonstrated in the old dome in 1846; and there is no occasion more appropriate than the anniversary observance of that momentous event to make known new discoveries that may still further contribute to the relief of suffering in man.

PROGRESS OF ANTITYPHOID INOCULATION.

IN the issue of the JOURNAL for July 21, 1910, we published an editorial on the "Advisability of Antityphoid Inoculation," in which we advocated the use of this means of protection by "all whose regular work or whose recreation during the summer season may expose them to unusual risk of typhoid infection." An article by Major George H. R. Gosman, of the United States Army Medical Corps, in the *Journal of the American Medical Association* for Oct. 1, reinforces this suggestion

and recommends even more extensive employment of antityphoid inoculation.

After a summary of the work on this subject previously done in other countries, Dr. Gosman points out the significant fact that of 8,510 cases inoculated by United States Army medical officers up to June 1, 1910, not a single one has since developed typhoid fever, in spite of varied exposure, whereas in the remainder of the army, among unprotected persons exposed to similar conditions, there have been in the same time over 200 cases of typhoid. The same favorable results are reported by other observers who have employed the typhoid vaccine prophylactically. At the Massachusetts General Hospital during the past year, since the beginning of systematic inoculation of all persons coming in contact with typhoid patients, not a single case of typhoid has occurred among nurses or ward tenders. This is the first year in which there have been no such cases.

The importance of these facts seems very great. It has been fairly demonstrated that antityphoid inoculation is absolutely safe, causes but trifling discomfort, and affords a considerable degree of protection against the disease. Its possibilities in the treatment of typhoid carriers, and of the disease in its active state, remain to be determined. It may well be that in it we have an agent whose widespread use may greatly diminish the endemic incidence of the disease and reduce typhoid fever to a place with diphtheria and smallpox in the category of controlled infections. Such a consummation would not only save human life and suffering, but would remove a standing disgrace to preventive medicine and to modern civilization. Under such circumstances we do not hesitate to urge upon members of the profession in the strongest manner the more extensive trial and adoption of this valuable prophylactic agency.

THE HOSPITAL OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

The hospital of the Rockefeller Institute for Medical Research was thrown open for inspection by invited guests on Oct. 17, and by the public on Oct. 18, and now is ready to commence its regular work.

It is located on the grounds of the institute, at the foot of East 66th Street and the East River, and is one of the most perfectly equipped establishments of the kind in the world. Its architecture harmonizes with that of the older building, and in the space between the latter and the main hospital is the isolation pavilion, for the treatment of patients suffering from contagious diseases. Each room in the pavilion has glass walls and airtight doors, and there is no chance for the air in one room to escape into the room of another patient. The ventilation apparatus connects with the roof, and the air leaving a room is sterilized by steam on its way up through the ventilating tubes. In the main building, one whole floor is given up to the accommodation of patients who are in need of unusual quiet and who can be looked after better in separate rooms. Landscape architects are now beautifying the surrounding grounds, and these will include tennis courts for the medical staff.

This new hospital will greatly enlarge the function of the institute, which has heretofore consisted of laboratory studies of physiological and chemical problems related to disease; pathological investigations of such affections as cancer, cerebrospinal meningitis, anterior poliomyelitis, etc.; and problems related to surgery. The following statement with reference to the hospital and its work has been given out by the management: "The purpose of the hospital is not that of merely adding seventy beds to the general hospital resources of the city of New York, but rather of being a place where an intensive study can be made of a few selected diseases. It has been supposed that a hospital connected with an institute for medical research would be one in which the patients were to be experimented upon, or used in the testing of novel remedies. It should be clearly understood at the outset that this hospital would have no right, and does not expect, to take any liberties with its patients in this respect. The treatment and cure of the patient will be the prime consideration in every individual case. The advantage to science which is expected from the establishment of the hospital will be derived rather from the unique opportunity of observing and treating disease. Of course, patients admitted to the hospital of the Rockefeller Institute will have a right to expect the advantage accruing from important discoveries and improvements bearing on the treatment of disease, but the obligation to safeguard the health of the individual will always be paramount. By the terms of the foundation of the hospital no charge will ever be made for services rendered to patients by the hospital, whether for medical attendance, drugs, nursing, board or lodging. Cases will be admitted solely because they fall within a class of diseases which, at a given time, it has been decided to treat in the hospital. The best service that the hospital can render will be given to every patient without regard to his poverty or wealth. Every physician

in the hospital is required to give his entire time to the work of the institute, to the exclusion of private practice, and even of consultation. This will insure an amount of careful medical oversight during the entire period of sickness which under ordinary circumstances would rarely be available."

It is stated that at the present time the diseases, cases of which will be admitted to the hospital, are pneumonia, anterior poliomyelitis, certain heart affections, and certain affections of disturbed metabolism. The medical staff is as follows: Director, Dr. Rufus T. Cole, formerly of the Johns Hopkins University; physician to the hospital, Dr. Christian A. Herter, at present professor of pharmacology and therapeutics in the Medical Department of Columbia University; resident physician, Dr. C. C. Robinson; internes, Drs. Draper, Swift, Marks and Peabody. All the last named have taken the ordinary course of hospital service and have devoted special attention to research work. Mr. Jerome D. Greene, well known through his recent services to Harvard University, is now the general manager of the Institute.

THE THERAPEUTIC VALUE OF RADIUM.

The presence in this country of Dr. Louis Wickham, Clinical Director of the Radium Institute in Paris, offers an apportunity for American physicians to learn from a leading authority the value of radium in the treatment of disease, especially of those forms usually referred to the surgeon or dematologist.

At the suggestion of Drs. J. C. White, J. C. Warren, F. H. Williams and R. H. Fitz, a special meeting of the Surgical Section of the Suffolk District Medical Society will be held on the evening of Monday, Oct. 31, at which Dr. Wickham will give those present the benefit of his wide experience in the clinical use of radium. Dr. Wickham is so well known to the physicians of this country through his numerous contributions to our knowledge of the subject, and by the courtesy which he has extended to those visiting his clinic in Paris, that, apart from the general interest in the subject, a large audience may be expected.

MEDICAL NOTES.

Conjunctivitis in Paris. — It is reported from Paris that a considerable epidemic of conjunctivitis is at present prevalent in that city, chiefly among the inhabitants of the poorer quarters. The nature and etiologic agent of the affection are, however, not stated.

Yellow Fever in Venezuela. — News from Puerto Cabello, Venezuela, reports a recent outbreak there of yellow fever. The number of cases is not stated.

Prosthetic Surgery in a Chicken. — An interesting example of the possibilities of veterinary prosthetic surgery is reported from Anderson, Ind. A chicken was recently hatched in that town with a congenital defect of the lower mandible, a sort of micrognathus, which prevented it from picking up its food. The local blacksmith took measurements of the incapacitated chicken, made a half-beak of tin, and wired it to the stub of the lower jaw. With this appliance the chicken is able to eat as well as with a normal beak, and is said to be holding its own in the struggle for existence as well as normal chickens without this unfortunate disability.

Tetanus Neonatorum in Hindustan. — At the recent Naini Tal Sanitary Conference in Hindustan, attention was called to the extensive mortality from infantile tetanus among the natives, especially at Campur. The prevalence of this disease is doubtless due to their custom of applying to the umbilical stump in the newborn a dressing made of mud, which, of course, contains tetanus bacilli in active culture. It will take centuries of education to eradicate the septic obstetric practises of some oriental peoples.

Another Gift to the Rockefeller Institute. — Mr. Rockefeller celebrated the opening of the new hospital attached to the Rockefeller Institute for Medical Research in New York with an additional gift of $3,820,000. This makes the total of Mr. Rockefeller's gifts to the Institute $8,240,000.

The occasion was further marked by the placing of the institution's property absolutely in the hands of the board of trustees, establishing it in the future as an independent foundation.

Pure Food Prosecution in England. — Prosecutions under food and drugs laws are not confined to our own country. In London recently a dairy company was fined £10, with 10 guineas' costs, for selling Gorgonzola cheese with a plaster rind composed of 13.8% of tallow and 86.2% of barytes colored with oxide of iron. This rind formed 21.7% by weight of the whole cheese, only 78.3% being genuine Gorgonzola. The court sustained the prosecution in its contention that the rind was not a necessary part of the cheese, and tended to render it not of the nature, substance and quality required by law.

Centennial of the University of Berlin. — The University of Berlin celebrated last week with appropriate academic ceremony the one hundredth anniversary of its foundation. A number of honorary degrees were conferred, several upon Americans. Among the latter recipients selected for this distinction were Associate Justice Oliver Wendell Holmes, who received the doctorate of laws; President Arthur T. Hadley, who received the doctorate of philosophy; and Prof. Theodore William Richards, who received the doctorate in medicine. Dr. Richards is professor of chemistry at Harvard College and in 1907 served as exchange professor at the University of Berlin. The exercises on the occasion of the celebration were attended by notable representatives of the *gelehrte Welt* from every part of Germany and from many foreign countries.

Status of the Cholera Epidemic. — During the past week, according to available reports, there have been 98 new cases of Asiatic cholera in Italy, and 30 deaths from the disease. One fatal case has also been reported as occurring in London, though the mode of its entrance has not as yet been determined. In the United States no further cases have been detected, but rigid precautions are still in force, and the local health officers of every city in which immigrants from Russia or Italy settle have been requested by the Federal Immigration Bureau to keep all such settlers under observation until all possibility of their developing the infection is passed.

Mission Hospitals in the Orient. — At the centenary meeting of the American Board of Commissioners for Foreign Missions, held in Boston last week, commendatory emphasis was laid by several speakers on the work accomplished by Christian hospitals in heathen lands. There are now such hospitals and dispensaries in eight of the principal cities of Turkey, and the charitable and medical relief afforded by these institutions in times of pestilence, famine and war have done much to conciliate and educate the people. At the Marathi Mission in India nearly 50,000 patients were treated last year by five American and two native doctors, and similar work is being done in Rahmi, Ahmednagar, Bombay, Wai and Sholapur. No foreigners are so much respected in India as American physicians and nurses.

Meeting of the Advisory Public Health Board. — The meeting of the advisory board of the hygienic laboratory of the United States Public Health and Marine-Hospital Service, to which we made editorial reference last week, was held at Washington on Oct. 10. The principal topics under discussion were the prevention of cholera, the control of poliomyelitis and the treatment of pellagra. Dr. Lavender, who was sent abroad last spring to study the latter disease in Italy, presented a preliminary report, the details of which have not yet been made public. The board, which is composed of Dr. Simon Flexner, of New York; Prof. William T. Sedgwick, of Boston; Victor C. Vaughan, of Ann Arbor, Mich.; Prof. Frank Westbrook, of Minneapolis, Minn.; and Dr. William Henry Welch, of Baltimore, acts on such occasions as a national council of experts in conjunction with the officials of the Public Health Service.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Oct. 18, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 15, typhoid fever 29, measles 8, smallpox 0, tuberculosis 49.

The death-rate of the reported deaths for the week ending Oct. 18, 1910, was 17.34.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 15, 1910, was 205, against 181 the corresponding week of last year, showing an increase of 24 deaths, and making the death-rate for the week, 15.94. Of this number 109 were males and 96 were females; 200 were white and 5 colored; 138 were born in the United States, 64 in foreign countries and 3 unknown; 51 were of American parentage, 126 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 3 deaths; scarlatina, 9 cases and 0 deaths; typhoid fever, 30 cases and 2 deaths; measles, 4 cases and 0 deaths; tuberculosis, 42 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 2, heart disease 31, bronchitis 3. There were 16 deaths from violent causes. The number of children who died under one year was 50; the number under five years, 64. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 83. Anterior poliomyelitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 3 cases and 5

deaths. Scarlet fever, 1 case. Typhoid fever, 1 case.

Deducting deaths of non-residents, the total is 174 and the death-rate is then 13.53.

TYPHOID FEVER AT HYDE PARK. — Since Sept. 6, 26 cases of typhoid fever, with 3 deaths, have been reported to the Board of Health at Hyde Park, Mass. No definite source of the infection has yet been determined, and investigation has shown no obvious contamination of water-supply.

SCARLET FEVER IN SOMERVILLE. — During the past week there has been an outbreak of scarlet fever in Somerville, Mass., which is, however, hardly extensive enough to deserve the name "epidemic." Eighteen cases of the disease have been reported, of whom 14 are in hospital and 4 quarantined at their homes.

POLIOMYELITIS IN RHODE ISLAND. — News from Providence states that during the past week four new cases and two deaths from poliomyelitis were reported to the Rhode Island State Board of Health, making a total of 24 deaths from the disease in that state during the current year. Quarantine against poliomyelitis has been recommended by the advisory board of the United States Public Health and Marine-Hospital Service, and has for some time been enforced throughout Massachusetts.

NORTHEASTERN DENTAL ASSOCIATION MEETING. — The sixteenth annual meeting of the Northeastern Dental Association will be held at Hotel Somerset in Boston on Oct. 20, 21 and 22. At the opening session to-day a paper was read by Dr. Charles K. Teter on "Nitrous Oxide and Oxygen." Among Boston dentists who will also present papers are Dr. Alfred P. Rogers and Dr. George H. Wright.

PURCHASE OF LAND FOR SOUTH DEPARTMENT. — An order has been passed by the Boston City Council, and approved by the mayor, authorizing the purchase of a tract of land on Southampton Street for the construction of new wards for the South Department of the Boston City Hospital. This extension is made necessary by the great overcrowding of the present wards of this department, in addition to which considerable sums were expended last year by the city for the treatment outside Boston of contagious cases that could not be accommodated at the City Hospital.

WORK OF THE BOSTON DISPENSARY. — At the annual meeting of the corporation of the Boston Dispensary last week, the report of the superintendent presented a record of notable activity on the part of this institution. During the past year, 31,799 new patients have been received at the central office and 11,087 in the districts. A total of 102,263 visits has been made at the central office and 20,387 in the districts. At the dispensary, 81,247 prescriptions have been filled; and 2,987 patients, of whom 1,000 were new cases, have been cared for by the Social Service Department. During this year, the Dispensary has also assumed charge of the Tyler Street Day Nursery.

DEPORTATION OF HOOKWORM PATIENT. — The patient with hookworm disease whose case we noted in the JOURNAL for Sept. 22 as under treatment at the Carney Hospital, South Boston, has been ordered by the federal health officials to be deported to the Cape Verde Islands, whence he came on Sept. 4 last. He was admitted to hospital with the disease six days after landing in this country, and must, therefore, have had it on his arrival, which renders him liable to deportation under national law.

CLOSURE OF MILK STATIONS. — The recent closing of several stations of the Boston Milk and Baby Hygiene Association, from lack of funds, is particularly unfortunate, since it not only stops the daily benefit done to patients, but to a considerable extent undoes the work already accomplished in building up the clinic and educating the mothers. In the absence of suitable milk and watchful supervision, the latter may be expected readily to slip back into the popular fallacies of infant feeding, with a corresponding increase of malnutrition and infant mortality. Fortunately the results are not likely to be as serious at this season of the year as in hot weather. It is earnestly to be hoped that before another summer sufficient money will be forthcoming to insure the full continuance and extension of this beneficent charity.

MILK TRANSPORTATION RATE COMPROMISE. — The conflict over the regulation of milk transportation rates in Boston, to which we referred editorially in the issue of the JOURNAL for Oct. 6, has been temporarily settled by compromise between the contractors and the railroad companies. The rates under the new agreement have not yet been made known, but it is expected that they will not be higher than those previously in operation.

Pending the announcement and trial of these compromise provisions, the Interstate Commerce Commission has deferred action on the complaints previously made by the dealers against the railroads. Whatever the result of the new arrangement, it is probable that the shipment rates and the market price of milk will before long again become subjects of legislative discussion.

Water Famine in Palmer. — In last week's issue of the Journal we made editorial comment on the dangers of scanty water supply, referring particularly to the unfortunate conditions then prevailing at Palmer, Mass. During the past week these conditions have not improved, and the local water company has issued an order forbidding the use of the reservoir water for other than drinking purposes. To provide some protection for the town in the event of fire, a fire-engine has been installed under temporary shelter near the Quaboag River from which it can pump water through 900 feet of hose to the center of the town. For bathing purposes water is also being pumped through 2,300 feet of hose from Burleigh brook. A scheme to provide a new supply of drinking water from artesian wells at Tennyville has been given up for the present owing to lack of sufficiently powerful pumping-engines. Unless nature soon comes to the relief of Palmer with a copious rainfall, it would seem that the town is still in a serious situation, which might be made critical by the outbreak of fire or of epidemic disease.

NEW YORK.

Typhoid and Diminished Water Supply. — In Westchester County there has of late been a considerable increase in typhoid fever, and this is attributed indirectly to the greatly diminished water supply, in consequence of the prolonged drought. On Oct. 7, Dr. Ernst Schmid, President of the Board of Trade of White Plains, issued a second warning against the use of the water from a stream called Davis Brook, to which, he declares, most of the cases in the village have been traced. This water has been shown to abound in typhoid bacilli.

Report on Ehrlich's "606" — Dr. A. L. Wolbarst, attending genito-urinary surgeon to the out-patient department of the Beth Israel Hospital and the West Side German Dispensary, has just returned from Europe with a supply of Ehrlich's "606," which was personally entrusted to him by Professor Ehrlich for testing the remedy in his public and private practise. While in Berlin he had the opportunity of observing the effects of this new treatment in some three hundred cases of syphilis, and he states that in the successful cases the promptness of the results often seemed quite marvelous, especially in instances of four or five years' standing which had resisted ordinary treatment.

A "Cholera Carrier." — A third case of cholera has developed in quarantine. This was reported on Oct. 9 by Health Officer Doty, the patient being an Italian thirty-six years old who arrived from Naples on the steamship *Moltke* one week previous. Dr. Doty states that the case shows all the features of the *Germania* case, and is undoubtedly one of the kind known as "cholera carrier." The *Moltke* left Naples on Sept. 21, and it was about seventeen days later that the man became ill with the disease.

New Medical Directory. — The new Medical Directory of the Medical Society of the State of New York, just issued, contains the names of 13,474 registered physicians in New York state, as against 13,023 in 1909; 2,558 in New Jersey, as against 2,458; and 1,384 in Connecticut, as against 1,304. In New York City there are 7,169, as against 6,889 in 1909, and 6,305 in the rest of the state, as against 6,134.

Conference of Sanitary Officers. — The 1910 Conference of Sanitary Officers of the State of New York is to be held at Buffalo on Nov. 15, 16 and 17, and the Health Department has been promised the assistance on this occasion of a number of sanitarians of national reputation. It is purposed to devote one day to the discussion of the relationship between health departments and various elements of society and another to communicable diseases, and to hold separate sessions for the consideration of certain problems affecting city and rural health officers respectively. There will also be an evening public meeting.

Lectures on Public Health. — In the course of a lecture at Columbia University on Oct. 10, on "The Development of Public Health Work," Dr. H. M. Biggs, Medical Officer of the City Health Department, stated that while many other American cities, especially the newer ones, had lately claimed a lower death-rate than New York, the statistics quoted in support of this claim were often untrustworthy. For one thing, the population of new places was being constantly increased by the advent in large numbers of new residents who were in middle life, and the death-rate in middle-aged persons was admittedly low.

Another explanation was to be found in the fact that many deaths in smaller cities are never reported, a matter of impossibility in New York. This was the first of an extended course of public lectures on public health problems and the prevention of disease to be given at Columbia on Monday afternoons, a series somewhat similar to that inaugurated last season, under the auspices of the university, at the College of Physicians and Surgeons. Among the other lectures in the course will be the following: "Water Pollution and Water Purification," by Dr. C.-E. A. Winslow; "The Collection and Disposal of Municipal Waste," by Dr. George Y. Soper; "Communicable Diseases — Their Transmission," "Communicable Diseases — Their Prevention," by Dr. William H. Park; "Some Examples of the Control of Infectious Diseases," by Dr. Simon Flexner; "The City Milk Supply and Its Control," by Dr. Ernest Lederle; "Tuberculosis — The General Problems, The Organized Campaign against the Disease," by Dr. Livingston Farrand; "Tuberculosis as a Social Problem, Methods of Treatment," by Dr. James A. Miller.

Mortality Statistics. — The weekly reports of the Health Department show that the mortality in the city during the month of September represented an annual death-rate of 14.48, as against 14.91 in August and 14.33 in September, 1909. The corrected death-rate for the month, excluding non-residents and infants under one week old, was 13.81. In the week ending Sept. 17, the uncorrected rate was only 13.58, the lowest recorded since the first week of November in 1908. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from whooping-cough declined from 9.25 in August to 4.25 in September; the weekly average from diphtheria and croup, from 19.75 to 13.5 (the lowest number recorded in years); from diarrheal diseases, from 268 to 190.75; from diarrheals in children under five years of age, from 255 to 181.25; from appendicitis and typhlitis, from 12.5 to 9; from Bright's disease and acute nephritis, from 90.75 to 87.75; and from puerperal diseases, including septicemia, from 12.25 to 10.75. Among the diseases in which there was an augmented mortality were the following: The weekly average of deaths from scarlet fever increased from 2.75 to 3.75; from pulmonary tuberculosis, from 152.75 to 159; from acute bronchitis, from 11 to 14; from bronchopneumonia, from 49.75 to 67.25; from cancer, from 70.75 to 74; from apoplexy and softening of the brain, from 14.25 to 18.75; and from organic heart diseases, from 89.75 to 108.75.

The total number of births reported in the state during the month of August was 18,049, while the deaths numbered 11,998, showing a net gain in native population of 6,051. Of this net gain, 5,157 were in New York City, where the births reported amounted to 11,207, as against 6,050 deaths. In the whole state there were 734 deaths by accident during the month, and of these, railroad fatalities were responsible for 159 and drownings for 138.

5. Pelton emphasizes the importance of early diagnosis in pulmonary tuberculosis, a disease which is making an appalling drain on public funds and private charity. Thousands of these patients might be supporting themselves if the disease had been diagnosed in the incipient stage. The chances for recovery are in direct ratio to the earliness of the discovery of the disease. In making an early diagnosis the writer considers the following points most important: (1) The anamnesis; (2) frequent examination of the chest; (3) careful observation for toxemic symptoms (evening rise of temperature, rapid pulse, loss of weight, anemia and debility); (4) the cutaneous tuberculin test; (5) x-ray examination of the chest; (6) as a last resort, tuberculin subcutaneously. In cases where sputum cannot be obtained, tubercle bacilli can sometimes be demonstrated in fasting gastric contents. Bacilli are rarely found in the stools unless the intestine is also infected. The inoculation of guinea pigs with sputum may establish a doubtful case. [L. D. C.]

3. Gwathmey writes a valuable paper on recent progress in anesthesia. From animal experimentation he can state

positively that the safety of all anesthetics is increased by the addition of oxygen and by warming. Warm chloroform and oxygen make a safer combination than ether and air. Heat is especially valuable in assisting rapid recovery from anesthesia, and in preventing nausea and vomiting.

Electric anesthesia is not yet sufficiently developed to be practical for clinical use. If it ever becomes so, it will be the safest anesthetic known.

The sequestration method of Dawbarn, which maintains anesthesia by cerebral anemia, deserves a more thorough trial; the only contra-indication is a weak heart.

More attention should be paid to anesthetic shock. All patients need preliminary treatment, both mental and medicinal, in order to eliminate the psychic element. Preliminary medication should consist of morphine, either alone or with hyoscine or chloretone. Small doses of morphine given sufficiently ahead of time will generally prevent stimulation of the vomiting center before, during and after full surgical narcosis, and the anesthetic can be discontinued much earlier. [L. D. C.]

3. McCoy writes an interesting paper on the occurrence of bubonic plague among ground squirrels in California. In 1908, when a few cases of plague occurred in San Francisco, the possibility that squirrels as well as rats might carry the infection was suggested. During the past two years the writer and his associates have examined 90,000 squirrels pathologically; 300 of them were found to be infected. In some districts the ratio was as high as 1: 10. Since 1908 there have been 12 human cases in which evidence pointed conclusively to squirrels as a causative factor. At present, therefore, the indication is to exterminate the ground squirrel as well as the rat in infected districts. [L. D. C.]

8. Savitz has studied the history of the Alaska Indians and finds that they have been visited with several plagues during the past forty years. In 1869, an Indian trading with white men in British Columbia contracted measles and took it back to his countrymen. All the tribes were afflicted in large numbers, both children and adults; the mortality was 33%, most of the deaths being due to a complicating pneumonia. In 1872 smallpox raged among these people with frightful mortality; most of the fatal cases died before the eruptive stage. In 1876 there was a serious epidemic of influenza. In 1888 there was a second epidemic of measles, and in spite of the enlightened work of missionaries, 20% died, many of a complicating diphtheria. Tuberculosis has probably always been with them. [L. D. C.]

5. Gosman speaks of antityphoid inoculation very hopefully. Not only does it reduce the number of cases, but when a case does appear in a patient who has been inoculated (which is rare, however), the course of the disease is much milder. This is found true from 8,510 inoculations in the United States and German armies. A great stride has been made by the successful treatment of a typhoid carrier by Stone, and the number of cases developing in nurses and ward tenders at the Massachusetts General Hospital has been greatly lowered following Spooner's inoculations, which have resulted in the important fact that this is the first year that no typhoid has originated in the Massachusetts General Hospital. English statistics show that immunity will last three years, which will cover the time of most campaigns, also the training courses of nurses and house pupils. Severe reactions are few and the injection is believed to be harmless. Further systematized inoculation of soldiers and hospital attendants is strongly urged as a routine.

6. Nichols and Fordyce give a detailed description of the composition, dosage and uses of Ehrlich's new syphilis remedy, the so-called "606," or synthetic arsenobenzol, a drug which had for its purpose the destruction in a single dose of all the parasites, leaving the host uninjured. Clinical results seem to show that this remarkable drug can do this. Too short a time has elapsed, however, to warrant the statement that no relapses ever occur. His stated that within twenty-four to forty-eight hours of the injection of the drug, superficial lesions, such as mucous patches, condylomata and primary lesions, are free from living spirochetes. The drug is a yellowish powder which rapidly oxydizes on exposure to air, and is, therefore, put up in vacuum tubes. It dissolves in water with difficulty, making a strongly acid solution. The administration is as a neutral base or an alkaline salt, deep into the muscles, into the veins or under the skin. The dose is 0.3 to 0.6 gm., and is dissolved in 1 to 2 ccm. of sodium hydrate solution. Acetic acid is then added, drop by drop, till the base precipitates out in the form of a fine yellowish suspension. This precipitate is collected in from 1 to 2 ccm. of sterile distilled water and $\frac{1}{10}$ normal sodium hydrate added, or 1% acetic acid as needed, until the reaction becomes precisely neutral to litmus. According as the reaction is or is not accurately neutral, the injection will be followed by much or no pain. Clinically this drug has been tried at the Blackwell's Island Hospital. Results showed that whereas before the treatment the serum reactions were all positive, at the expiration of a certain time, three or four months, all the reactions became negative.

The dose was found to be nearer 0.6 than 0.3 for beneficial results. This drug is not generally available at the present time. [E. H. R.]

1. Holt, from his researches, believes that the bacillus influenzæ is the causative agent in many cases of obscure high temperature in cases of recurrent bronchopneumonia or pneumonia running an unusual course, or of high temperature persisting in cases of otitis in which the ears have been opened, or after surgical operations, especially in the winter and spring months.

3. Jones and Hamilton report an interesting series of cases of hemiplegia, mostly following diphtheria, but some in other acute affections. They state that peripheral paralyses occur in diphtheria in as high as 5 to 15% of the cases, while hemiplegias are very rare, 3 in 800 cases in the Berlin Charity Hospital. Osler found none in 120 cases. Taylor states that the causes of infantile hemiplegia in order of frequency are: Acute encephalitis, thrombosis (arterial or venous), hemorrhage and embolism. In diphtheria, antitoxin does not seem to have lessened the cases of paralysis, either of central or peripheral origin.

8. Lord has made valuable investigations into the etiology of actinomycosis. He suggests that the failure of actinomycosis to develop at other than body temperature, the lack of any convincing evidence that it is a contagious disease and the prevailing location of the affection about the jaws and neck, suggest that infection arises from within the individual and probably from the mouth. He has demonstrated the presence of organisms which have all the characteristics of actinomycosis from smears taken from the teeth and tonsils of patients without actinomycosis. This was confirmed further by guinea pig inoculation. [E. H. R.]

1. Robertson and Chesley, after reviewing the literature relating to the pathology of acute anterior poliomyelitis, give their own findings in 6 cases. The pathological process, they found, extended from the perivascular lymph-channels of the anterior portions of the cord into the surrounding tissue spaces of the gray matter and into the lymph-channels of the white matter and pia. The exudate at first consisted of small numbers of polymorphonuclear leucocytes, but soon these were replaced by endothelial cells and lymphocytes. The tissues became edematous and in places infiltrated with lymphocytes. The blood vessels were congested and showed fatty degeneration of their walls. The hemorrhage following rupture of these degenerated areas seemed to be the agent most responsible for the destruction of tissue. Stains for micro-organisms were negative, and inoculation of animals merely confirmed the opinion that Geirsvold's diplococcus is not a causative factor in the disease.

2. Hopkins, examining the blood of a patient with pernicious anemia after transfusion, found an active phagocytosis of red cells by polynuclear leucocytes. He discusses the reason for this, but does not reach a definite conclusion.

8. Frank attempted, by use of the corpus luteum of ten sheep, to bring about changes in the uterus of castrated rabbits. His results were negative, leading him to believe that the use of ovarian extract of a heterologous species, as it is now prepared, does not replace the secretion of the removed gland.

9. Gay and Lucas found that the acute stage of anterior poliomyelitis, both in human beings and in monkeys, is characterized by the occurrence of a distinct leucopenia, with relative increase of eosinophiles and lymphocytes.

In spinal fluid from monkeys, during the incubation and prodromal stages, the number of cells is increased, the increase being first of the mononuclear type, later of the polymorphonuclear. A fibrin clot appears during prodromal and early stages, but disappears later.

There was never any evidence of the presence of antibodies in the serum or spinal fluid of monkeys with the disease, nor in the spinal fluid of human beings with poliomyelitis. [G. G. S.]

1. In an address before the Royal Society of Medicine on "Vaccine Therapy," Wright first discusses the rationale of this procedure; he describes the recent history of medicine as it has affected bacteriology. He deplores the fact that the average clinician does not and cannot do much of his own bacteriologic work, but merely delegates it to the laboratory man. He discusses the limitations of vaccine therapy first as stated by the clinician and again as contended for by the bacteriologic worker. He mentions various conditions, such as x-ray dermatitis, pruritus, hay fever, gastric disturbances, which the clinician

claims are quite beyond the reach of vaccine therapy, but which have shown marked improvement by this method.

He goes on to discuss the limitations as contended for by the bacteriologist, the relation of the opsonic index to inoculation, whether this index can be accurately measured or not, and whether or not it can be dispensed with. The general subject of the value of vaccine therapy and the mode of administration of the vaccine he speaks of briefly. [J. B. H.]

1. McGavin gives the details of 18 cases operated on under Jonnesco's combination of stovaine and strychnine injections in the spinal canal. His results are, on the whole, disappointing: 4 successful cases show that high puncture is a possibility, but do not suggest that this method will ever take the place of general anesthesia. Other cases of high puncture show its great dangers.

6. In discussing the prevention of shock, Rowell considers ether, given by the open method, as one of the biggest factors; the next best means in his opinion is the injection of salt solution under the skin. Extract of the infundibular portion of the pituitary gland (20% solution) he has found of great value in raising blood pressure, its effect lasting twelve to twenty-four hours or longer.

Crile is of the opinion that, in abdominal operations especially, handling of the intestines is a large factor; careful anesthetization and conservation of blood will help to prevent it. Fear itself he believes is a considerable factor in producing shock. He describes what he believes to be the proper method of preparing a patient mentally for an operation and of giving ether.

7. Blumfeld, McCardie, Ryall and others, discussing spinal anesthesia, seem to agree that this method is retrogressing in favor and that, though it will always be of value in selected cases, as our methods of giving an anesthetic by inhalation improve, spinal anesthesia, on account of its numerous dangers, will be less and less used.

13. In discussing the value of teeth in the human economy, Turner goes so far as to say that teeth are largely for beauty, and that as far as digesting and assimilating food is concerned, they can quite well be dispensed with. Mummery, Cryer and others were unwilling to take this radical view, but believed that carious teeth should be removed and that absence of teeth was better than carious teeth. [J. B. H.]

2. Fordyce, A. D. *The Care of the Infant and Young Child (to Five Years) in Edinburgh.*
3. *Dick, R. J. *Acute Pancreatitis Considered in Relation to Three Cases Occurring in General Practice.*

1. Hall and Beattie describe in detail a case of what they call chronic interstitial pneumonia. The case is a remarkable one in many ways. During the entire course of the disease, nearly four months, in spite of constantly increasing lung involvement, the pulse never reached 100; the temperature ran a practically normal course and there were no signs of right-sided cardiac dilatation; the patient slept better lying flat than sitting up. There are some excellent plates.

3. Dick gives the details of 4 cases of acute pancreatitis, presents a general summary of the subject, with remarks on diagnosis prognosis, and treatment. [J. B. H.]

13. Wertheimer-Raffalovich, R. *Experimental Investigation on the Effect of Pantopon.*

2. There has been considerable hesitancy on the part of the profession to use Ehrlich's new preparation for syphilis more than once in the same case. This is due to the fear of hypersensitiveness in the organism after the first injection. Wechselmann, however, has used second injections in several cases where the first did not clear up the symptoms and found that the second injection usually cleared up the remaining symptoms. He finds such an injection harmless at the eighth day, but considers that three to four weeks is the better time to give it, as it seems to have more effect.

11. Gerber has been investigating leprosy with a view to finding out the lesions in the respiratory tract and the dangers from its secretions. He does not find leprosy bacilli in the upper air passages of healthy people attendant upon those with this disease, nor in patients who have no lesions in the upper air passages. Lesions in the nose and throat, however, are very common, and when they occur the bacilli are present in the excretions in great numbers and frequently to the exclusion of other bacteria.

2. *COSTANTINI, G. *Primary Sarcomata of the Liver.*

2. Costantini presents a clinical and pathologic report of two cases of primary sarcoma of the liver, and collects from the literature a series of 111 similar cases previously reported, including one from this JOURNAL [March 9, 1871, vol. vii, p. 157]. Of these, however, he rejects 60 as proving on examination to have been probably instances of hepatic metastasis, and 9 not accessible in the original for verification. Of the remaining cases which he considers authentic, more than 25% occurred in the first decade of life, and the next largest number in the third decade. Nearly 80% of the cases were males. Pathologically, the author believes that such tumors may arise from perivasal, cirrhotic or pericystic connective tissue. [R. M. G.]

4. ZAPELLONI, L. C. *The Anatomic and Physiologic Relations between Rats in Parabiosis.*

2. Sabella reports a case of early lumbar Pott's disease treated by laminectomy under stovaine spinal anesthesia with removal of the left transverse process of the fifth lumbar vertebra, the only portion of bone appearing to be the seat of definite tuberculous process. The dura was exposed and found to show incipient tuberculous pachymeningitis, but was not opened. The patient was entirely relieved of pain within a few days, made a rapid convalescence, and seven months after operation is reported as being without recurrence of symptoms, able to walk and with perfect functional restoration of the sphincters. The author believes that such surgical intervention is indicated in a limited number of discreetly selected early cases as offering the hope of shortening convalescence by permanently eradicating the disease process instead of waiting for it to become arrested by spontaneous healing. [It should be added that the case in question was particularly favorable from the limitation and accessibility of the tuberculous process.] [R. M. G.]

Obituary.

HENRY HAMMOND GALLISON, M.D.

HENRY HAMMOND GALLISON, M.D., M.M.S.S., who died of cerebral hemorrhage last week at his home in Cambridge, Mass., was born in Boston on May 20, 1850. Though early interested in painting, he entered the Harvard Medical School, from which he graduated in 1872. He then went abroad to pursue his study of art, and remained there for some years, chiefly in Paris. During this time he became an artist of considerable distinction, and his paintings gained admission to the *salons* of Paris, Turin and London. After his return to this country, he spent his summers at Annisquam, where he owned a pleasant country house and studio, and his paintings were familiar at exhibitions in Boston and in other cities of the United States. His greatest work was perhaps in the decoration of the Ray Memorial at Franklin, Mass. Since 1908 he had been partly paralyzed from a slight premonitory hemorrhage, but had borne his disability with characteristic serenity and fortitude.

Many who knew Dr. Gallison did not know that he was a physician; but those who knew him well felt that his medical affiliation added a value to his temperament that it could not otherwise have possessed. His life is evidence that artistic tastes and talent are not necessarily killed by medical study, and his memory is one which our profession may be glad to share with that to which he was chiefly dedicated.

Miscellany.

MASSACHUSETTS MEDICAL SOCIETY.

PROCEEDINGS OF THE COUNCIL, OCT. 5, 1910.

WALTER L. BURRAGE, *Secretary.*

A STATED meeting of the Council of The Massachusetts Medical Society was held in John Ware Hall, in the Boston Medical Library, Oct. 5, 1910, at 12 o'clock, noon, the President, Dr. George B. Shattuck, in the chair, and seventy-seven Councillors present.

The record of the last meeting was read and accepted.

The secretary stated that, in accordance with custom, he had taken the oath of office for the current year.

The following were appointed delegates to the meetings of state societies:

Vermont State Medical Society: O. J. Brown, North Adams; N. P. Wood, Northfield.

Medical Society of the State of New York: D. E. Keefe, Springfield; E. P. Joslin, Boston.

Dr. Goss, for the Committee on Membership and Finance, recommended that the resignations of thirteen members be accepted; that two be placed on the retired list; that fifty-five be deprived of the privileges of fellowship for nonpayment of dues.

Voted, That the report be accepted and its recommendations adopted.

Dr. C. H. Cook presented a report, as a delegate to the meeting of the National Legislative Council of the American Medical Association, held in Chicago, Feb. 28 and March 1 and 2, 1910, in which he summarized the four important papers read to the Council and their discussion. He stated that Dr. Frederick R. Green, secretary of the Bureau of Medical Legislation, has secured

copies of all public health laws of the various states, with a view to the publication of a handbook on medical legislation. Also that a report on optometry and one on medical expert testimony, both written by Dr. George W. Gay, had received the unanimous approval of the Council, and the publication of the former in pamphlet form had been recommended. Dr. Cook urged the need of an awakening of the medical profession to a much fuller and clearer realization of the responsibilities of the medical man as a citizen, not only of a state, but of the nation, and asked the co-operation of the members of The Massachusetts Medical Society with the delegates to the National Legislative Council.

Voted, To accept the report and place it on file.

The committee appointed to consider the petitions of Drs. Maurice Gerstein, of Roxbury, and William I. Wiggin, of Lowell, to be restored to the privileges of membership, reported favorably, and the reports were accepted.

Dr. Walter P. Bowers, of Clinton, was appointed a member of the Committee on State and National Legislation, to succeed Dr. G. W. Gay, resigned.

Dr. E. W. Taylor made a motion that the President of the Society appoint a chairman and a secretary for the surgical section and for the medical section for the current year. The motion was discussed by Drs. Goss, Withington and Hugh Cabot, and it was so voted.

Also, it was

Voted, That the question of the method of appointing the officers of the sections of the Society at the annual meetings in the future be referred to a committee of three, appointed by the President, to report to the next stated meeting of the Council.

The President appointed Drs. E. W. Taylor, Lund and Cotton as this committee.

A petition from Dr. Charles Henry Crawford, of Lawrence, to be restored to the privileges of membership, was read by the secretary, and the following committee was appointed to consider the petition: Drs. G. S. Allen, R. M. Birmingham and H. W. Manahan.

A similar petition from Dr. Flora Frost Moody, of Springfield, was referred to the following committee: Dr. H. W. Van Allen, Dr. Sarah M. Wilbur and Dr. D. E. Keefe.

On motion of Dr. O. F. Rogers it was

Voted, That the Committee on Medical Diplomas be instructed to revise the list of medical colleges recognized for the purpose set forth in By-Law I and report to the next stated meeting of the Council.

Dr. G. W. Gay spoke on the partisan character of the testimony of some of the medical experts in the courts, and made a motion that the secretary call the attention of the members to this matter, requesting the Fellows of the Society to notify the Committee on Ethics and Discipline of any departure from ethical standards of which they may become cognizant, and it was so voted.

Dr. H. D. Arnold presented a report as a delegate to the House of Delegates of the American Medical Association, and pointed out the great importance of the work of the House of Delegates, and urged the full attendance of all the delegates at the annual meeting of the American Medical Association.

Voted, To accept the report and place it on file.

Dr. Hugh Cabot made a motion that the next annual meeting of the Society be held in Worcester. After an animated discussion by Drs. Cotton, G. E. Francis, H. Gage, L. F. Woodward and others, and amendment by Dr. Crowell, it was

Voted, That the matter be referred to the Committee of Arrangements, to report at the next meeting of the Council.

Correspondence.

TEWKESBURY; GLOUCESTER; CHEPSTOW; MONMOUTH; RAGLAN; ROSS; HEREFORD; WORCESTER; SHREWSBURY; CHESTER; LIVERPOOL UNIVERSITY.

[*From Our Foreign Correspondent.*]

LIVERPOOL, Sept. 19, 1910.

Mr. Editor: The country on the borderland between England and Wales seems to have been particularly associated with episodes in the civil wars of British history. The reason for this is hardly obvious unless it be that the fastnesses of the Welsh mountains have always afforded good refuge for defeated insurrectionists, for non-conforming dissenters or for deposed sovereigns, and a point of vantage for pretenders, revolutionists and intriguers of every description. In any event, many of the important battles of the Revolution (an Englishman knows only that of 1688), and of the Wars of the Roses, were fought in these parts, and the castles of the region suffered recurrent sieges by Royalists and Parliamentarians until all of them were ruined and many of them swept out of existence in the process. If Henry VIII must be blamed for the pillaging of all the abbeys, priories and shrines in England, Cromwell and his Roundheads have as much to answer for in their destruction of ancient fortresses and in the vandalism with which they visited cathedrals and churches throughout the land.

The first of these names connected with the English civil wars is Tewkesbury, a town of very different character and connotation from its American namesake, situated not far above Gloucester on the river Severn. One can go to it by boat, and the sail is very pleasant, even though one fail, as we did, to see the nymph Sabrina, who must have been driven under cover by the rain of the preceding night. One lands at a picturesque ford called the Lower Lode, and walks thence to the town across the "bloody meadow of Tewksbury." Here in 1471 was fought the decisive battle in which Edward IV defeated the Lancastrian forces and established the house of York on the English throne. In the brooding quiet of the spacious old abbey across the fields is buried Edward, Prince of Wales, killed in this battle, and also the Duke of Clarence, brother to Edward IV, who later met the ignominious though even more celebrated death of being "drowned in a butt of malmsey," a fate and mode of demise which one would have thought best suited to Sir John Falstaff. Sir John apparently knew Tewkesbury, too, for he averred of Poins's wit that it was "as thick as Tewkesbury mustard." Unhappily he died before the days of the battle, when Prince Hal as king "ran bad humours on the knight"; had he lived to engage in that memorable fight, the issue of the conflict might have been different. We could not discover, in the pleasant little tea-garden where we lunched, that Tewkesbury mustard was thicker than that of any other locality. Nor would one dream, in walking over them, that the smooth, green meadows

which slope gently from the town and abbey to "Severn's reedy marge" were ever wet with the blood of those whom "false, fleeting, perjur'd Clarence slew on the field at Tewkesbury."

Another name intimately associated with English history is that of Gloucester, now a busy but agreeable port at the mouth of the Severn. There was no battle here, but in 1643 the town held out successfully against the Royalists. This exhibition of "malignity" was not forgotten by the Stuart adherents, and after the Restoration, the fortifications of Gloucester were utterly destroyed. There is, therefore, little of interest now in the city but its splendid cathedral. Here is buried Edward II, the first Prince of Wales, son of Edward Longshanks, the great castle-builder. Here, too, is a monument to Edward Jenner, the discoverer of vaccination, who was born in the neighboring town of Berkeley. It is a gratification to professional pride, as well as to better sentiments, to find him thus in the company of bishops and kings.

Not far from Gloucester, on the marches of South Wales, is Chepstow, whose extensive castle once guarded the mouth of the Wye and the old Roman road that still serves as a highway of travel across the river into the country beyond. This castle was held for the king in the days of Cromwell, and later served for twenty years as a prison for the regicide Martin. During those years of solitude he composed his epitaph, which may now be read over his grave in the Chepstow church. With rude but impressive nobility, these lines express his justification for his action and, like his dungeon in the ivy-grown, rambling old ruin, "appeal from tyranny to God."

At Monmouth, a short distance up the winding Wye, one comes again to associations of an earlier date. Here in 1388 was born Prince Hal, Falstaff's merry royal comrade, the hero of our finest historical drama, who later, as Henry V, conquered France and set a French princess beside him on the throne of England. The room where he was born is still shown among the scanty fragments of Monmouth Castle, and his statue, much worn and obliterated by time and weather, occupies a prominent place on the front of the town hall. Another character indelibly associated with Monmouth is that of Geoffrey, the imaginative chronicler of the twelfth century, whose romancing records, though so full of fable, constitute our most valuable information of what the history of his time ought to have been. The river Monnow, which here flows into the Wye and gives the town its name, is spanned by a bridge that resembles those at Bruges and looks as if it had been transported out of medieval Europe. Gray called Monmouth "the delight of the eye and the very seat of pleasure," and indeed it is to-day perhaps the most picturesque of English border-towns and a center for many fascinating excursions. One of the most charming of these is to Raglan, on the whole the most perfect and beautiful of ruined English castles. Like Chepstow, it was a seat of the Earls of Worcester, later Dukes of Beaufort, and, like Chepstow, was held by them for Charles I. In fact, Raglan was the last Royalist stronghold to be captured by the Parliamentary troops, who wreaked their vengeance by undermining and blowing up its beautiful moated Cæsar tower, which as a result now resembles the *gesprengte Turm* at Heidelberg. Partly perhaps in remembrance of its loyalty, partly no doubt on account of its charm and beauty of environment, it was visited after the Restoration by Charles II, whose apartments, fronting on the lovely Fountain Court, constitute the finest part of the ruin. If one could visit but two castles in England, Raglan should surely be one of them.

A little further up the Wye from Monmouth is Ross, chiefly familiar to us from Pope's verses to John Kyrle, the "Man of Ross," who became an eminent philanthropist on five hundred pounds a year. Judging by professional incomes of the present day, this should not have been so difficult a task, especially since money in those times, like George Washington's dollar, "went farther than it does nowadays." Whatever the benefit of Kyrle's philanthropy may have been to his contemporaries, he is chiefly blessed by the present generation for having planted two centuries ago the elm trees whose vigorous maturity now shades the wide churchyard of Ross. Among many quaint memorials in this quiet "God's acre" is one in Latin on the tomb of Richard Panter, who departed this life in 1733, which in spite of its uncanonical and inaccurate meter and rhyme, seems to have a touch of satirical dignity and distinction that makes it almost classic:

> "Animula vagula blandula,
> Hospes comesque corporis,
> Quae nunc abibis in loca
> Pallidula rigida nudula,
> Nec ut soles dabis jocos."

It is to be hoped that these lines were intended not to cast aspersions on the deceased Panter for unseemly habitual merriment, but merely as a mournful comment on his customary cheerful Christian temper. Not far from this monument is another, a simple cross erected in 1637 to mark the burial in a common grave of 315 victims of the plague, and bearing in addition the pathetically fervent inscription, "Libera nos, Domine!" It is hard for us to realize now the poignant terror of these ancient epidemic scourges. One of the interesting preventive measures taken in the seventeenth and eighteenth centuries against the "pestilence that walketh in darkness" was the custom of whitewashing the interiors of churches throughout. As a procedure of antiseptic cleanliness this may have had some slight efficacy, but incidentally it rendered the much more valuable service of preserving to posterity a wealth of carving and frescoes which might hardly have escaped the destructive energies of the Georgian era but for the successive layers of obscuring whitewash, the removal of which has afforded occupation for the zeal of a more artistic modern generation of restorers. The church at Ross affords admirable example of beauties thus long concealed and now once more brought to light. Of the town itself there is little to be said except that it is old and somewhat shabby and evidently having a rather hard time trying to live up to its reputation and environment. Its situation is almost ideal — on the concave bank of one of the numerous bends or horseshoes from which the "devious Vaga" derives its name. On the opposite, convex bank or tongue, which broadens out into a richly green, low-lying, fertile meadow, stand the ruins of Wilton Castle, insignificant in itself, but interesting to us as having once belonged to Thomas Guy, the founder of Guy's Hospital in London, to which institution he bequeathed the property. The castle has now passed into other hands, and its walls, overgrown with reddening woodbine, form the chief attraction of a handsome private estate. Just beyond the castle, the Wye is crossed by Wilton Bridge, on which is a rather unusual four-way vertical sundial, with the admonishing motto:

> "Esteem thy precious time
> Which pass so swift away,
> Prepare then for Eternitie,
> And do not make delay."

Doubtless in a less critical age this laudable injunction lost none of its force from the grammatical license of its second or the anticlimax of its fourth line.

Still further up the Wye is Hereford, a very pleasant and prosperous city, and chief town of the county of the same name, "which for wheat, wool, and water yieldeth to no shire in England." It also manufactures much cider and a seductive drink called perry, which we did not sample. There is a fine cathedral at Hereford, and several interesting old churches, and in the outskirts of the town a hospital or almshouse for old soldiers and other pensioners, founded in 1614 on the site of a former priory of Black Friars. In the garden are still some ruins of this priory, among them a well-preserved preaching-cross, from which the monks used to hold open-air evangelistic services, somewhat in the fashion of the Salvation Army of to-day. In one of the suburbs on the opposite side of the town is the so-called White Cross, erected in 1349 to commemorate the staying of the Black Death of that year, another of the medieval pestilences which seem to have swept this region with particular severity. Of the later civil wars Hereford, though always loyal to the Crown, seems to retain scarcely any trace. It is associated with the Stuarts in another way, however, as the birthplace of Nell Gwynne, the famous beauty and actress, and favorite of Charles II. In an obscure lane, and on the very wall of the bishop's garden, too, is a brass tablet marking the

site of the cottage where she was born, and recording her as the "founder of Chelsea Hospital and mother of first Duke of St. Albans." This somewhat tactless addition cannot help reminding one of the story how one day, when Charles had refused her request to ennoble their child, she promptly suspended the infant by the heels over the balustrade of the balcony on which they were sitting, and remarked, "Over he goes if you don't provide for him." "No," said Charles, "don't hurt the Duke of St. Albans." And so the royal peerage was established. Perhaps this episode was quite in accord with the character of the monarch "who never said a foolish thing and never did a wise one." At any rate, one cannot help thinking more leniently of him for his dying injunction to "take care of poor Nell." She is buried at St. Martin's-in-the-Fields, in London, among many with better reputations and less virtue than herself.

At Hereford we left the valley of the Wye and struck across country to Worcester. This journey took us through Malvern, famous as a health-resort on account of its mineral springs, but more interesting as the site of the monastery where William Langland wrote his "Vision of Piers Plowman." Unfortunately it was a dismal, rainy day when we traversed the scene, very different from the "May mornynge in Malverne hilles" on which the tale begins. Beyond the hills one comes again to the Severn valley and to Worcester, chiefly famous for the manufacture of the somewhat miscellaneous staples: porcelain, gloves and Worcestershire sauce. There is an architecturally interesting cathedral here, in which, by the way, we noted the epitaph of one Richard Solly, "who was seised with an inflammation of the intestines which in five days terminated his life," evidently a case of fulminating perforative appendicitis with general peritonitis. Worcester also has its association with the Stuarts, to whom it was always loyal. There is still standing in excellent preservation a fine old Elizabethan mansion, called the Commandery, from its earlier association as a hospice or infirmary of the Knights Templar, in which Charles I stayed on a visit to the town. This same house Charles II later made his headquarters for a time in 1651; here he spent the night before the battle of Worcester; and from an upper window witnessed the defeat of his troops in that memorable engagement. From that same window one can still overlook the battlefield, and one is shown the very trap-door through which the young monarch made his precipitate escape on the approach of Cromwell. There is enough old oak carving and furniture in this house to drive an antiquarian into a frenzy of admiration.

The journey from Worcester to Shrewsbury takes one back again to Plantagenet times, for here in 1403 Henry Bolingbroke, father of Prince Harry of Monmouth, won his great victory over the Earl of Northumberland. It was this battle in which Harry Hotspur was killed and in which Falstaff fought his "long hour by Shrewsbury clock." The abbey church looks much the same as it must have on that occasion, though its clock is modern, and probably a better timepiece. The town itself, whose name is happily mitigated from that of Scrobbesbyrig, in which it used to rejoice in Saxon times, contains a number of old houses, in one of which Henry Tudor, Earl of Richmond, is said to have passed the night before the battle of Bosworth, which, in 1485, terminated the Wars of the Roses and made him Henry VII of England. There is also in Shrewsbury the ancient and celebrated grammar school which in different ages has harbored two such diverse geniuses as Sir Philip Sidney and Charles Darwin.

Last and in some respects most interesting of these border-towns is Chester, which ever since Roman days has been an outpost at the Welsh frontier on the north, as Chepstow is at the south. As capital of Cheshire one associates it chiefly with cats and cheese; the latter is delectable, but the former, though numerous and amiable, seem to have lost their traditional grin. Perhaps the most distinctive characteristics of Chester, which give so many Americans their first impression of England, are its old frame houses, with their arcades and projecting upper stories, and its town-walls, the only ones in the country that remain complete, though perhaps not so interesting as those of York or of Conway. One can make the entire circuit of the city walking on top of them, and see much of interest in the journey. From the Phœnix Tower, at one angle of the walls, Charles I watched the defeat of his army at Rowton Moor, on Sept. 24, 1645, and the tower now contains a museum of relics associated with him and with the battle. The town itself held out for the king for another year, but finally surrendered to the Parliamentary besiegers. Chester had a former reputation for endurance in a losing cause, for at the time of the Conquest it was the last English city to yield to William the Norman. A little further along the walls, near the river Dee, is the Water Tower, once washed by the tide and used as a mooring-place for ships, now left high and dry by the deposit of silt and the damming of the river higher up. Near this Water Tower have been discovered a number of stumps of columns from some Roman structure on this site, which resemble gigantic mushrooms as one looks down on them from above. Still further on, by the Bridgegate, one obtains splendid views of town and river, and can go down thence to the ruins of St. John's Priory, whose crumbling red sandstone, sunk deep in ivy, makes a picture for the eye and the imagination as well. Chester Cathedral, too, is a study for the artist as well as a first lesson to the beginner in ecclesiastical architecture. Among its many monuments to soldiers, one wonders which bears the name remembered by the

"Widow in sleepy Chester
Who mourns for her only son";

but Subadar Prag Tewarri is not there to tell. Several Cheshire regiments were sent to America in the "good old colony days," and the names of Louisburg and Quebec are conspicuous on their records and standards. Some of these tattered old flags were carried at Bunker Hill, but the name of that battle is not mentioned. Among so many warriors, it is pleasant to find the peaceful grave of Ralph Higden, the monk who is supposed to have written "Everyman." It is to be hoped that the "Dethe" which summoned him proved less terrible than the grinning skeleton of the old miracle.

From Chester to Liverpool is like a step from the Middle Ages back to the familiar atmosphere of our own day and generation. The busy streets, the smoke-grimed buildings, the sharp contrasts of wealth and poverty, all bear evidence of the evils of our civilisation as well as of the good that has grown out of them. As a city, modern Liverpool is dominated by the memory of Gladstone, whose statue before St. George's Hall, like that in the Strand in London, recalls vividly the bristling, indomitable figure that so long stood at the head of the greatest nation in Europe. If popular government has done nothing else, it has at least developed great democratic leaders from the days of Oliver Cromwell to our own.

The return to Liverpool marks the end of our happy and profitable holiday, and recalls professional duties and interests. We sail to-morrow, and shall soon "leave old England on our lee." In our brief time at Liverpool we have been able to make only a hurried inspection of some of the medical institutions in the city, chiefly those connected with Liverpool University, whose buildings form a huge group of structures, not so extensive as the immense Imperial Institute at London, but reminding one of it, nevertheless. There is a large general hospital, a dental hospital, a lying-in hospital, a skin hospital, a school of hygiene and splendid laboratories, among them notably those of the School of Tropical Medicine. It is impressive to visit such an institution, and consider the battle it is fighting for the sordid dwellers in the slums which surround it and for all mankind as well. The spirit of that conflict speaks eloquently in the tablet of dedication on one of the buildings:

"To the Glory of God, in the knowledge of Whom are the steps of human progress, and to the memory of William and Catharine Johnston, now beyond the shadows of time in life eternal, one of their sons erected these laboratories for the search after the mystery of life in health and sickness, and for the alleviation and prevention of suffering."

Such words are a noble reminder of the duties of a profession whose inspiration is the same wherever there is human welfare to be served. One feels the readier to return and labor humbly at home for having met and known some of those who are forwarding the same great cause beyond the seas.

MEDICUS PEREGRINUS.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 5, 1910.

BANKS, CHARLES E., surgeon. Directed to assume temporary charge at Portland (Quarantine), Me., during the absence of Surgeon J. M. Eager. Oct. 1, 1910.

EAGER, J. M., surgeon. Directed to proceed to Naples, Italy, upon special temporary duty. Oct. 1, 1910.

NYDEGGER, J. A., surgeon. Detailed to represent the Service at the meeting of the Medical Society of the State of Pennsylvania, to be held in Pittsburg, Pa., Oct. 4-6, 1910. Sept. 29, 1910.

LAVINDER, C. H., passed assistant surgeon. Granted seven days' leave of absence from Oct. 1, 1910.

GRUBBS, S. B., passed assistant surgeon. Granted fourteen days' leave of absence from Sept. 25, 1910, on account of sickness.

MCCLINTIC, T. B., passed assistant surgeon. Granted seven days' leave of absence from Sept. 28, 1910, under paragraph 191, Service Regulations.

RUCKER, W. C., passed assistant surgeon. Directed to proceed to Elizabeth, N. J., upon special temporary duty. Sept. 28, 1910. Leave of absence for ten days from Sept. 14, 1910, amended to read seven days from Sept. 15, 1910.

PORTER, JOSEPH Y., quarantine inspector. Leave of absence for thirty days from Sept. 20, 1910, revoked.

BEAN, L. C., acting assistant surgeon. Granted five days' leave of absence from Oct. 1, 1910.

GUSTETTER, A. L., acting assistant surgeon. Granted six days' leave of absence from Oct. 1, 1910.

HALLETT, E. B., acting assistant surgeon. Granted seven days' leave of absence from Oct. 1, 1910.

MCDANIEL, S. E., acting assistant surgeon. Granted fourteen days' leave of absence from Oct. 18, 1910.

MCLARTY, A. A., acting assistant surgeon. Granted seven days' leave of absence from Oct. 3, 1910.

SMALL, E. M., acting assistant surgeon. Granted eight days' leave of absence from Oct. 3, 1910.

TAPPAN, J. W., acting assistant surgeon. Granted twenty days' leave of absence from Oct. 1, 1910.

TOWNSEND, F., acting assistant surgeon. Granted four days' leave of absence from Oct. 6, 1910.

WETMORE, W. O., acting assistant surgeon. Granted one day's leave, Sept. 19, 1910, under paragraph 210, Service Regulations.

KEEN, W. H., pharmacist. Granted seven days' leave of absence from Sept. 19, 1910, under paragraph 210, Service Regulations.

OTT, C. R., pharmacist. Granted twenty-nine days' leave of absence from Oct. 11, 1910.

BOARD CONVENED.

Board of medical officers convened to meet at Stapleton, N. Y., Oct. 7, 1910, for the purpose of making a physical examination of a cadet of the United States Revenue Cutter Service. Detail for the board: Surgeon H. W. Austin, chairman; Passed Assistant Surgeon W. A. Korn, recorder. Oct. 4, 1910.

SOCIETY NOTICES.

EIGHTH MASSACHUSETTS STATE CONFERENCE OF CHARITIES. — The eighth conference will be held at Fitchburg, on Oct. 26, 27 and 28.

PARKER B. FIELD,
279 TREMONT ST., Boston. *Secretary.*

SUFFOLK DISTRICT MEDICAL SOCIETY. — Stated meeting, Saturday, Oct. 29, at 8.15 P.M. "What Medical Societies can do for the Health of the People." Paper: By Mr. John Ritchie, Jr. (For two years member of the Boston Board of Health.) Discussion: Formal discussion by invited guests will be omitted; instead, it is hoped that there will be free general discussion by the members of the Society. Business: Election of Nominating Committee. Revision of the By-Laws of Suffolk District Medical Society. Refreshments after the meeting.

GEO. H. MONKS, *President.* DAVID D. SCANNELL, *Secretary.*

RECENT DEATHS.

GALLISON, HENRY HAMMOND, M.D., M.M.S.S., died in Cambridge, Oct. 12, 1910, aged sixty years.

DOWLING, CHARLES JOSEPH, M.D., M.M.S.S., died in Springfield, Sept. 26, 1910, aged thirty years.

DR. DAVID P. BUTLER, who died recently of endocarditis, at Rutland, Mass., was born in Boston in 1873, the son of a physician. He received his medical degree from Boston University in 1898, and for some years had been in charge of the Rutland Cottage Sanatorium for Tuberculosis.

DR. JOHN VEITCH SHOEMAKER, who died of nephritis, at Philadelphia, on Oct. 11, was born in Chambersburg, Pa., on March 18, 1852. He graduated from Dickinson College in 1872 and from the Jefferson Medical College in 1874. He was for a time demonstrator of anatomy at the latter institution, and in 1876 became lecturer on anatomy and diseases of the skin at the Philadelphia School of Anatomy. Later he was for some years senior physician to the Medico-Chirurgical Hospital, Philadelphia, and surgeon-general of the National Guard of Philadelphia. Professionally he was perhaps best known for his numerous contributions on dermatology and therapeutics to various medical journals. He is survived by his widow.

DR. DE FOREST WILLARD, who died on Oct. 15 at Lansdowne, a suburb of Philadelphia, was born in Hartford, Conn., in 1846. He was for many years professor of orthopedic surgery at the University of Pennsylvania, and at one time president of the American Orthopedic Society and of the American Surgical Society.

CHOLELITHIASIS.

BY RICHARD P. CHASE, M.D., BOSTON.

I HAVE realized for some time that, of the patients referred to me with digestive disturbances, a considerable per cent of them, comparatively, have gall-bladder affections, most often gallstones. So on looking over my records I was not surprised to find that in every one hundred patients there were from five to nine whose symptoms were attributable to cholelithiasis. I am of the impression that I find this condition as often, perhaps more often than any other, the cause of secondary digestive symptoms. Since about 70% of my patients are referred by physicians, and the balance of them have usually been treated by several physicians before coming to me, I have come to the conclusion that cholelithiasis is more often mistaken for primary digestive diseases by the general physician than is the case with any other organic disease. It is not, of course, the typical cases of gallstones that are mistaken, but those cases lacking one or more of the usual symptoms upon which reliance is placed in diagnosis. As in peptic ulcer, it is usually hemorrhage that is wanting, so in gallstone disease we find it is usually jaundice. I have arrived at this conclusion because, of the cases referred to me, jaundice has been observed in less than 5% of them. Since it is the absence of this symptom that seems to be the chief stumbling in diagnosis, it occurs to me, and, in fact, I have been quite convinced through various experiences with physicians relating to this feature, that the very large per cent of gallstone cases not presenting the symptom of jaundice is far from being fully realized. Furthermore, for the foregoing reason, it follows that the very common occurrence of cholelithiasis is not duly recognised.

Now, of all autopsies, gallstones are found in about 7%, — Moynihan says approximately 10%, — while in autopsies of persons over sixty years of age they are encountered in 25%, or, in other figures, one person in every four over sixty years old has gallstones. It is evident, then, that cholelithisis is of very common occurrence. More common, is it not, than the reader realized? Just what per cent of patients having gallstones present symptoms, it is difficult to determine. We do know, however, that when symptoms occur it is most often between the thirtieth and fiftieth year of life. We also know that gallstones are three or four times more common in women than in men. A full realization of these facts, combined with the knowledge that the symptoms arising from gallstones are, in the main, of a digestive type, will, I believe, lead one to more often think of this condition, and to think of it as a common cause of digestive disturbances. Moreover, a realization of the fact that jaundice occurs in probably less than one third of the cases of gallstones will render one far less dependent on this symptom in diagnosis than appears to be the case at the present time.

Moynihan says: "Patients refer their trouble to the stomach and not to the liver. It requires the unmistakable evidence of jaundice to associate the suffering with gallstones in the minds of all patients and of not a few medical men, yet jaundice is an infrequent and inconstant symptom of gallstones." Richardson says: "Many practitioners to-day believe that jaundice is essential to the diagnosis of gallstones. In the great majority of cases jaundice is anatomically impossible."

As stated, the symptoms of cholelithiasis are, in the main, those of "indigestion," and it is for this reason that these cases are referred to the internist for diagnosis or treatment. Before referring to the gastric symptoms and findings, let me say a few words regarding some of the other symptoms of cholelithiasis.

Colic is, to the patient and physician, the most prominent symptom; its character is generally well known, though modifications in its severity, duration and location may at times puzzle one. Many physicians seem to believe that the pain is located in the gall-bladder region and only there, but very often (Ewald says in most cases) the pain is referred to the stomach; it usually extends through to the back, and, according to Murphy, "in seven cases out of ten it is referred to the right subscapular region," occasionally to the left. Besides biliary colic, it should be understood that there are very few conditions which cause recurrent attacks of violent pain in the region of the gall bladder or in the epigastrium. Mixter says: "It is important to recognize the fact that recurrent attacks of pain in the region of the liver almost always mean gallstones. If one goes on that idea, and with a history of frequent recurrent attacks of pain makes an exploration, it is very seldom that he goes wrong." Pain frequently, and tenderness of the liver almost always, follow the colic, and in many cases the liver is found enlarged, at least for a few days; occasionally it is found constantly enlarged.

Regarding the tender area on the right side behind, on a level with the twelfth dorsal vertebra, and extending at times to the posterior axillary line, described by Boas.[1] Moynihan says: "I consider the search for this tender area a necessary part of the examination. . . . It is undoubtedly a sign of great value." Rarely, it seems, can the gall bladder be palpated. I was surprised at Moynihan's statement that "I have once been able to feel a gall bladder filled with stones and at operation to verify my observation." I had thought that palpation of the gall bladder was of more frequent occurrence than the above statement would seem to indicate. In one such case I recall, the patient could feel the tumor, and she stated that it always swelled at night, — probably due to its increased bile content at this time. The gall bladder contained over one hundred stones and several ounces of mucopurulent fluid.

[1] Münch. med. Wochenschr., April 18, p. 604.

JAUNDICE.

Brewer states that jaundice was absent in from 80 to 90% of all his operative cases of gallstones. Murphy has found this symptom present in only 14% of his cases at any time during the course of the disease. Different writers give various figures. However, it is very evident that this symptom is not observed as often as is generally believed. Since the symptom is absent in so many cases, it loses much of its diagnostic value. With the progress in internal medicine, we should be well past that point where it was once considered necessary to delay the diagnosis of gallstones until the appearance of jaundice, the diagnosis of peptic ulcer until hematemesis occurred, and the diagnosis of gastric cancer until the appearance of the cardinal symptoms.

Jaundice when present usually occurs only after one to several days from the beginning of the colic, and in many cases may then be detected only by careful examination of the sclera, the urine and the feces; in some cases it does not last longer than forty-eight to seventy-two hours. This symptom is certainly often overlooked. In many cases the colic subsides after the administration of morphine, so that by the following day the patient feels practically recovered, and the physician may not see the patient a second time, thereby missing his best opportunity of obtaining a history, of palpating for tenderness and enlarged liver, etc. He has quit the case agreeing perhaps with the patient's own diagnosis, "acute indigestion" due to some article of diet which the patient is usually prepared to name. If the patient has had stomach trouble in the past and is subject to similar attacks, the diagnosis may seem all the more plausible. With a recurrence of the attack, which comes sooner or later, unless jaundice happens to be detected, the same diagnosis is probably again made. Thus the case goes on; if stomach symptoms are present between attacks, the patient is treated for the same until the physician at length discouraged with his lack of success refers the patient to an internist, or, as often happens, the patient takes matters in her own hands and seeks one.

When the patient reaches the internist, he, or more often she, is subjected to a careful history and physicial examination. The history alone is usually sufficient to direct one to the probable diagnosis. Remember that on the internist's history blank there should always be the word "colic," and that questions regarding the same should be asked. The internist knows that the forty or more simple articles of diet mentioned by the patient as the causes of her attacks do not as a rule in any digestive disorders cause sufficient epigastric pain to necessitate the use of morphine, hence he thinks of other causes. Herein he has an advantage over the general practitioner. But to prove the presence or absence of gastric disease, the stomach must be examined. Dr. Richardson says: "The distinction between gallstones and gastric diseases is chiefly important because under a wrong diagnosis of organic disease we may operate uselessly, as in simple dyspepsia, gastralgia, atony, gastritis and the like. On the other hand, we may, under a wrong diagnosis of functional disturbance, withhold an imperative operation for gastric cancer, ulcer, strictured pylorus or gallstones."

Such distinction can be made only by careful observation of the patient, in some cases for a month or six weeks' time, and by the intelligent employment of all the known methods of gastric examination. Besides differentiating from gallstones the various gastric diseases mentioned, it is also necessary to determine the gastric conditions accompanying gallstones, and particularly in those patients declining operation, that proper treatment for both conditions may be administered.

Some patients with gallstones have digestive symptoms only during attacks of colic and for a few days thereafter; others have them both with and between attacks. In the latter cases the symptoms tend to increase in severity as time goes on.

STOMACH FINDINGS.

Immediately following an attack of biliary colic one most often finds a diminution or absence of HCl, and also that the stomach does not empty itself in the normal length of time. These findings show that both the secretory and motor functions of the stomach are impaired. In many cases after a few days or weeks these functions are restored to the normal, yet in some cases several weeks of dietetic, medicinal and mechanical treatment are necessary to restore them. In many cases several weeks after an attack of colic we find the stomach normal, or possibly an occasional hyperchlorhydria; on the other hand, we not infrequently find true cases of secondary chronic gastritis, with the absence of HCl and other usual findings. Frequently repeated attacks of colic, with inflammation in and about the gall bladder, probably most often brings about this condition through interference with the blood supply of the stomach. Adhesions from the gall bladder to the pylorus at times produce severe cases of gastric dilatation. Thus it is seen that various gastric conditions accompany cholelithiasis. In most cases removal of the gallstones, the breaking up of adhesions, etc., overcome all symptoms, so that the medical treatment of these various conditions becomes necessary only in those cases declining operation. The per cent of patients, however, declining operation for their gallstones is a pretty large one. In some cases of gastritis accompanying gallstones, the condition may be entirely overcome by medical treatment, and lesser disturbances are more quickly and more easily relieved. Proper treatment directly following attacks of colic undoubtedly prevents the development of many of these troublesome digestive disturbances.

Lavage of the stomach is one of the best methods by which to overcome recurrent vomiting, so annoying and, in some cases, so threatening to the patient's life. Lavage at times will stop biliary colic as well as morphine, and it is the

best of methods in treating gastritis, atony and dilatation. The rules for the dietetic, hygienic and medicinal treatment are much the same as those that govern the treatment of like conditions due to other causes.

In a differential diagnosis, besides the gastric conditions already mentioned, we have particularly to consider gastric crises, renal colic and Dietl's crises, appendicitis in its various forms, pancreatitis, angina pectoris, affections of the right lung and pleura, and other diseases of the liver.

The average case of cholelithiaisis is not difficult of diagnosis, yet in some cases a differential diagnosis is extremely difficult and at times impossible by medical means. In some patients with apparently clear symptoms of gallstones, no stones are found; in other patients gallstones are found as the cause of trouble where least expected, but these are the exceptional cases.

We should not forget that there are many persons who have gallstones and yet have never presented the usual symptoms. It is without doubt among this class of patients that we should seek the cause of many of the obscure reflex gastric conditions.

TREATMENT.

First and foremost it should be understood that stones in the gall bladder probably cannot be dissolved by the administration of medicine. Certain experiments have yielded just sufficient results to lead the hopeful to believe that time and perseverance in the use of certain agents may accomplish this desired result, but abundance of clinical experience fails to prove that such is the case. We cannot in any case guarantee to ward off or delay an attack of colic, yet in many cases it certainly seems as if such result is attained, as there is no recurrence for years. Confinement to bed after an attack of colic until inflammatory conditions have subsided should be insisted upon. Kolisch believes that by careful attention to diet, medication, etc., and abstinence from sports and other forms of violent exercise for one year after the colic, latency of gallstone disease is frequently obtained. As to medicinal agents for the gall-bladder conditions and the usual digestive disturbances, I know of none better than some such combination as that recommended by Billings, as follows:

℞. Sodii Salicylatis,	1.0
Sodii Phosphatis,	2.0
Sodii Sulphatis Exsic.,	6.0

M. Sig. 3ss to 3j in glass of hot water thirty minutes before meals.

The general attitude of both physicians and surgeons regarding operative procedure in most cases of cholelithiasis is too well fixed to warrant much discussion. Those physicians, however, who feel it their duty to advise operation in every case as soon as the diagnosis is made, and who have not done so, may find some consolation in the statement by Richardson: "I have not a few patients in whom I know gallstones to exist, and in whose cases I have not as yet advised operation. Knowing, however, to a certainty that stones are present in the gall bladder, knowing also the precise anatomical conditions present, I am prepared to advise operation the moment the first symptom of impaction appears, unless this impaction should be of the briefest and most trivial character."

FURTHER OBSERVATIONS ON THE WASSERMANN REACTION FOR SYPHILIS.

BY WM. P. BOARDMAN, M.D., BOSTON.

SINCE the first publication concerning the so-called Wassermann complement fixation test for syphilis in 1906, the test has been performed by many investigators on thousands of cases of syphilis, and in other diseases of all sorts, so that a fairly conclusive idea of its limitations in certain directions may now be had.

In spite of much careful scientific work on the subject, the theory upon which the reaction is based is still obscure.

Though many modifications have been suggested to simplify the method, and though a majority of these give a higher percentage of positive results in syphilitic cases, the most of them have also been found to give positive results in many non-syphilitic cases and are, therefore, useless. In regard to the suggestion of H. Schlimpert,[1] which is also used by Noguchi in his book on serum diagnosis, and according to which the reagents are used in small amounts, the method remaining otherwise the same as in the original Wassermann reaction, this scheme has a distinct advantage in that it uses less blood from the patient and less guinea pig's blood. In regard to Noguchi's own modification, using a human-rabbit serum for amboceptor instead of the sheep-rabbit of the Wassermann test, and small amounts of the patient's serum without inactivation, enough has already been done with this to show that it, like the many other modifications, gives a higher percentage of positive results in syphilitics, but, like the others (though not nearly as often), it gives occasional positive results in non-syphilitics.[2] I have had no opportunity to try this test except in about twenty-five cases, and in these it gave the same results as the Wassermann; except in one case of a perforating ulcer of the foot, in which the Noguchi was positive and the Wassermann negative. But this series is obviously too small to be the basis of any personal conclusions.

My own results with the Wassermann reaction, based on a little over 500 cases, are with the original Wassermann technic except that I used an

[1] Deut. Med. Wochenschr., vol. xxxv, no. 32, p. 1386.

alcoholic extract of normal liver as antigen. The blood in practically every case was taken from the patient's ear (about 1.5 to 2 ccm.), which was found to be the simplest method for obtaining blood in the average case.

I have tabulated all my results as positive or negative, classifying all doubtful or slight reactions as negative, so that my figures show a rather low percentage of positive results, but I think I have very seldom erred in reporting a positive reaction in a non-syphilitic case, as one is liable to do if he does not adhere fairly closely to this classification.

I have arranged the following table to show in a general way the percentage of positive reactions obtained by some other investigator in the various broad classes, making possible a comparison of these figures with my own.

Of syphilitic cases I have examined the blood in 267 cases, including parasyphilitic and latent cases.

Of these, 23 were primary lesions showing no secondary manifestations. Eleven of these, or 49%, were positive. As has been very generally found by other investigators, most of the positive results were found in the cases of long duration, — over three weeks, — the reaction sometimes not appearing until the fifth or sixth week, and even later in a few cases. My percentage is much lower than that shown in the table of collected cases from the literature, and I account for this by the fact that many investigators have classified among primary lesions those in which the chancre is still active, but in which secondary manifestations have already appeared; such cases I have classed among the secondary cases. My results show clearly that in the earlier primary lesions the search for the spirocheta pallida is a much more reliable test, but in the older lesions, especially those in which the chancre has been treated locally, or has nearly or entirely healed over, the spirocheta is very seldom found and it is just at this time that the Wassermann reaction begins to become positive and the patient is getting restless over the long wait for secondary manifestations to appear.

In secondary cases showing lesions at the time of examination I have tried the reaction 59 times on 57 patients, with 49 cases giving a positive and 8 a negative reaction, or 86% positive. Omitting treated cases, there were only 2 negative in the series, giving 98% positive. One of these two was a case showing a macular rash on the forehead and severe headache, both of which cleared up under anti-syphilitic treatment. The other was a beginning secondary eruption which gave a positive reaction a short time later, showing that the antibody is very late in appearing in occasional cases.

In tertiary cases showing manifestations at the time the test was made there were 88 cases, 78 positive and 10 negative, or 88.6% positive.

Among the negative cases 2 were very chronic cases of lesions of the nasal septum which had persisted for years with frequent exacerbations and more or less frequent courses of treatment. One case was a perforating ulcer of the foot diagnosed as syphilitic clinically. Three were cases of cerebral syphilis and one an old case of leukoplakia who also showed a serpiginous tubercular syphilide on the leg, both of which were much benefited by subsequent treatment. The others were all cases which had received considerable antisyphilitic treatment.

In cerebral syphilis, 8 of 11 cases, or 77%, were positive. This is higher than has generally been found by other investigators, whose figures were as low as 16% in one series. I think that this may be due to the fact that some of the cases where the diagnosis was rather uncertain clinically have been classified under the list of cases of doubtful diagnoses in my series which possibly should belong to this class. I have only had 4 cases of spinal syphilis, all of which were positive.

Of latent cases, meaning by this term patients who gave a sure history of syphilis or showed unmistakable scars of syphilis, but no active syphilitic lesions at the time of examination, there were 51; 23, or 45%, of which were positive. This corresponds fairly well with the average found in the literature. The earlier cases, that is, those within three years of the primary infection, were only 23% positive. This includes many cases which had been under long and careful treatment, which accounts for the low percentage. The cases of more than three years' duration, including some very old cases who were undoubtedly completely through with the disease, showed 51% positive results. The literature does not bear out these figures of mine, probably showing that my series is far too small to allow definite conclusions. Of 1,423 early latent cases in the literature, 724, or 51%, were positive, and of 1,164 of the late cases, 534, or 46%, were positive. But in the latent cases much depends on the amount of treatment which has recently been undergone and somewhat on the length of time since the last appearance of symptoms of the disease, so that little inference can be drawn from these general figures.

The congenital cases I examined numbered 17, and all but one were positive, or 95%. This was the fetal blood from the placenta of a syphilitic infant who showed definite syphilitic lesions and a positive test two or three weeks after birth. This supports the view generally held that congenital syphilis will almost invariably give a strong positive reaction, but that at birth we may get a negative result due to the fact that the antibodies have not yet developed in the blood.[1]

In contrast with this, it is curious to see how late in life the positive reaction persists, as when an interstitial keratitis develops. I have examined 9 cases of this disease (generally accepted as being due most always to congenital syphilis), and found 7, or 78%, strongly positive. One of the negatives was in a child who was supposed to be tuberculous and gavé a strong Von Pirquet reaction, and the other in an elderly woman forty-five years of age. Some of the positive cases were in young women seventeen or twenty years of age.

Of tabetics, my series contains but 22 cases, and only 6 of these, or 27%, showed a positive reaction. Several of the others showed a slight or doubtful reaction, but, as elsewhere in my list, I have classed all such cases as negative. The percentage falls much below that obtained by other authors, for which I can find no adequate reason, except that the number of cases may be too few to draw definite conclusions.

I have only had an opportunity to try the test on two cases of general paresis, and both were negative. Both were very early cases, possibly still doubtful in diagnosis, and it is in these early cases that the negative results are most commonly obtained.

The non-syphilitic cases numbered 161 and included nearly all the more common diseases of the skin and internal organs. Taking up those diseases in which occasional positive results have been reported; first is scarlet fever, of which I have examined 9 cases, all negative, though a few of them did show a very slight reaction, especially just following the fall in the temperature. There was no doubt in my mind, however, but that these were not strong enough to be classed as positive results. Seven cases of malignant disease were all negative, including some cases with marked cachexia.

In pulmonary tuberculosis I have had 8 cases, all but one very advanced. Three of these gave a positive reaction, but on analysis one was an Italian who could give no history on account of his inability to talk English, one a colored man from whom the blood was taken at autopsy and whose clinical record showed a very shady past, though no signs of syphilis were found at autopsy, and the third was a young man who had been with the army in Cuba and the Philippines and admitted having gone through several attacks of gonorrhea and chancroid, but denied ever having had a hard chancre or other signs of syphilis. Neither of these three cases gives much support to the statement made by some authors that advanced tuberculosis often gives a positive Wasserman reaction, though it undoubtedly does so in occasional or rare cases. In severe acute infections, including sepsis, pneumonia and typhoid, I have had uniformly negative results, but I have only examined a few such cases.

As regards treatment and its effects on the reaction, I have had very little opportunity to follow cases along to see when the reaction disappeared under treatment, and still less to find out when the reaction appears after cessation of treatment. All I can say is that on the basis of 53 cases which had received from a few days' to several years' treatment, only 2 showed a negative reaction who had received less than two months' treatment, and a few remained positive for several years under more or less constant treatment. The latter were either cerebral or congenital or very intractable cases of other forms.

[1] Wechselmann: Deut. Med. Wochenschr., vol. xxiv, no. 15, p. 665.

In general, the more energetic the treatment, whether with mercury or potassium iodide, the more quickly the reaction becomes negative. After cessation of treatment, the reaction often becomes positive again after a very variable time, most commonly with the recurrence of fresh symptoms of the disease. Though no definite figures are at hand, I am of the opinion that it is well to wait a few months after a long course of treatment before trying the reaction in cases where the question of prognosis and completeness of the cure is being worked out. Even after a several months' wait after cessation of treatment, the negative reaction does not have very much definite value. It seems to me, however, that it is one more point on which to base our conclusions as regards a complete cure when considered with the other points found by history and clinical examinations. Another curious effect of treatment which I have seen in one case and which is mentioned by K. Donath[4] is that in some untreated cases of syphilis which give a negative reaction, ten days' to two weeks' treatment is followed by a positive reaction. My case was one of a perfectly evident syphilitic throat lesion which gave a negative reaction at first; then, after about ten days' treatment, a slight reaction which was not strong enough to call positive, and, a week later, the patient still being under mild mixed treatment, a strong positive reaction was obtained. Donath suggests that this may be comparable to the so-called "*provakatorische*" reaction in primary syphilis by which an injection of mercury during the primary stage of the disease sometimes brings out a syphilitic rash within a day or two.

Of special cases which seem to me worthy of record I would mention one of three weeks' duration which healed up rapidly under local treatment with a mild dusting powder, but showed a strong positive reaction shortly after that. The physician who sent me the case agreed that in spite of no other signs of the disease the lesion might have been a hard chancre on account of my positive finding. In another week the chancre had broken down again and a typical syphilitic roseola was present on the body. I think that I speak fairly when I say that without having this positive reaction the average physician would have told this patient that his trouble was not syphilitic and no longer kept him under observation.

In three cases of enlarged liver, all diagnosed as ordinary cirrhosis, the strong positive reaction led to the diagnosis of syphilitic liver, and all three improved at once under antisyphilitic treatment, which latter would probably not have been instituted had it not been for the positive Wassermann reaction.

The diagnosis of syphilitic orchitis was made through the aid of a positive reaction in another case, and the operation for "sarcoma of the testicle" in this patient's case was indefinitely postponed.

Now as regards the value of a positive reaction: About the only diseases which have been found in the literature to give a positive reaction with any great degree of regularity seem to be frambesia, trypanosomiasis and leprosy, and only very rarely does one find a positive reaction in other conditions outside syphilis. The only exceptions that I have seen mentioned in the literature are occasional cases of advanced tuberculosis, and severe septic conditions just before death, rare cases of scarlatina, especially just following the defervescence, malaria, especially a few days after the chills have ceased, and very rarely malignant disease, especially those showing a high degree of cachexia. Certainly from a clinical standpoint in this locality, with the exception of malignant disease, very few of those cases are liable to cause confusion with syphilis in diagnosis. Even in malignant disease a positive result is so rare that it suggests a possible old latent syphilis in addition, in some of the cases.

I, therefore, maintain that a positive reaction has very definite value and almost invariably means syphilis past or present, and in the earlier stages usually means an active lesion.

In regard to the negative reaction, much less definite conclusions can be drawn. In primary syphilis, where so many cases are negative anyhow, even though the lesion be a month old, the negative reaction has no value, though in the latter cases it may be slightly more to be depended upon than in the earlier ones when taken in connection with the clinical features of the case. In active, untreated, secondary lesions, however, the reaction is positive in such a very high percentage of cases that I think a negative reaction means that the lesions are almost surely non-syphilitic, though perhaps not absolutely so. In progressing tertiary lesions the percentage of positives is so high that we can say that a negative reaction has nearly the same definite value, but in cases of very long standing, such as an old leg ulcer of many years' standing, or an old lesion of the nasal septum, one is very apt to get a negative reaction, so that in these cases it has very little value. But in any case of supposed tertiary syphilis it is better to consider the negative finding in conjunction with the clinical evidence and even resort to the therapeutic test, though, as is well known, this also fails in some of these cases of very long standing. In latent cases the negative reaction by itself has little value, as in primary syphilis, for only about 50% are positive in such cases. But with a very indefinite history and no objective signs of a previous syphilis, it seems to me that a negative reaction is still another help in ruling out the presence of syphilis in a doubtful case.

In supposed congenital cases showing lesions at the time of examination, a negative reaction practically rules out syphilis and is of great value, for nearly every case of congenital syphilis showing lesions will give a strong positive reaction, and this even in spite of considerable treatment.

In general paresis it is generally stated that the reaction is nearly always positive, but most of the figures are drawn from cases in insane hospitals where only advanced cases are to be

[4] Berl. Klin. Wochenschr., vol. xlvi, pp. 2015–2017.

found. Unfortunately, however, in the earlier ones where the diagnosis is still doubtful, the reaction is often negative, so that to depend on a negative reaction here would be quite misleading.

In treated cases one very seldom finds a positive result directly after the usual two or three years of careful treatment, but six months or so later it may help to show whether the disease has run out or not, and even more so if the test is repeated again after another six months' interval, watching the patient meanwhile for any clinical evidence of exacerbation. But I have not been able to produce figures to show the value of applying the test in this way, though it is being tried in several places.

Finally, in syphiliphobia I have seen most gratifying results follow (up to date at any rate) the finding of a negative reaction which gives these poor sufferers something much more definite and tangible than the mere opinion of their physician based on his careful observations. And right here I might mention one of these cases previously diagnosed as syphiliphobia which showed a very strong positive reaction and suggested to me the possibility of a sound and sane basis for the complaints of a few of these discouraging cases.

CONCLUSIONS.

A positive reaction is obtained in a large number of syphilitic cases, and if one adheres to the original Wassermann technic a positive reaction in a suspected case means syphilis almost without exception. A negative reaction in a suspected secondary or tertiary or congenital case means that it is probably not syphilis, but the finding should be used with caution and only in conjunction with clinical evidence and not by itself alone. A negative reaction in a suspected primary case, except one of long duration, and in an early case of general paresis, has very little value. In treated cases it has very little value except some months after treatment has ceased. To sum up, I think we may say that in the Wassermann reaction we have a definite aid to diagnosis, but its value in treatment and prognosis has not yet been carefully worked out.

I am glad to have this opportunity to express my thanks to Dr. Mallory for the use of the City Hospital Laboratory, and to the Boston Board of Health Laboratory for their continued courtesy and their kindness in allowing me the use of certain apparatus. I also wish to thank the staff of the City Hospital and the numerous private physicians who have given me the clinical material in such abundance.

Sanatorium for Hollanders. — The Christian Benevolent Society for Consumptives has been incorporated to establish a sanatorium for the care of those suffering from tuberculosis. The institution will be located in South Denver and will receive Hollanders from all parts of the United States. The secretary of the institution is Rev. I. Van Dollen, Denver. — *Jour. Am. Med. Asso.*

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES F. PAINTER, M.D., AND ANDREW F. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

[Continued from No. 16, p. 606.]

LIPOMATA.

(Male Patients.)

Case 35. L. F., male, thirty-five, married. Operation, March 19, 1902.

A large quantity of fibrin and villous thickening was found throughout the joint; considerable cloudy fluid escaped. At the lower end of the joint wound a row of thickened fringes was found which were removed.

The outer side of joint was opened and a similar condition found. One large finger-like fringe was attached to the capsule in the upper outer part of the joint. The cartilage presented a fairly normal appearance as a whole, except for a few areas which appeared thinner than normal.

Convalescence uneventful.

Discharged April 12, 1902.

Case 36. C. F., male, fifteen, single. Operation, April 8, 1903.

Patient presents a similar condition in both knees. The right was operated upon. Numerous fringes were found, the largest of which was attached to the patellar aspect of the joint.

Convalescence progressive. No pain, temperature or discomfort.

The stitches were removed on the twelfth day. Ninety degrees of motion without pain present at this time.

Discharged April 24, 1902.

Patient refused operation on left knee.

Case 37. T. H., male, twenty-six, single. Operation, Aug. 31, 1903.

Numerous large fringes found and removed. Two incisions were employed for the purpose.

Stitches removed on the eighth day. Forty-five degrees of passive motion present; active motion about 30°.

Nov. 16, 1903. Knee motions normal.

Three months later patient was again operated upon for spurs of the os calcis. No subjective symptoms at this time referrable to knee-joint.

Case 38. A. F. S., male, thirty, single. Operation, Nov. 4, 1903.

Patient was suffering from a villous arthritis, probably of Neisser origin. When joint was opened, about 8 oz. of yellow fluid, viscid in character, were removed. A few short fringes were found attached to under surface of capsule.

Stitches removed on eighth day. In addition to the routine treatment, rubber dam was used at night.

Discharged Nov. 18, 1903.

Massage to thigh and calf continued at Out-Patient Department for several weeks.

April 4, 1904. Patient presents symptoms of foot strain. Plates, showers and exercises.

Aug. 31. Small amount of swelling present for some time, situated to left of the patella. A chart of the fluctuation in size of the knee at Out-Patient Department suggests a hydrops articuli of the intermittent type.

Case 39. F. A. L., male, twenty-eight, married. Operation, April 29, 1904.

Numerous villi found, in greatest abundance as a

sort of pannus about the posterior borders of the patella and along the edge of the external femoral condyle.

Very rapid convalescence followed removal.

Discharged May 14, 1904.

CASE 40. E. D., male, forty-one, married. Operation, May 11, 1904.

A large dark purple fringe found immediately upon opening the left knee-joint. The synovial membrane was thickened throughout. About 1 oz. of clear thick serum was evacuated, containing several pieces of soft, fatty tissue, the largest of which was the size of a pigeon's egg. These were evidently detached lipomata in a state of partial degeneration. Incision over inner surface revealed a small sessile lipoma.

The knee became swollen shortly following the operation. Considerable pain accompained this condition. Patient ran an atypical septic temperature with a leucocytosis of 20,000. A few days later a fusiform swelling appeared over the outer surface of the leg, and an incision was made over fluctuating area three days later. Beneath the muscles was found a quantity of slightly blood-stained pus. A second incision made over the posterior surface of the leg and a smaller quantity of pus of a similar nature found. Following this there was an amelioration of all the symptoms, knee symptoms subsided and wounds closed as rapidly as wicks would permit.

Discharged June 14, 1904.

Oct. 17. Patient had right knee operated upon and several lipomatous masses attached only by fibrinous adhesions were removed.

Stitches removed on seventh day. Motion restricted few degrees. Manipulated, under anesthesia, on tenth day, but patient regained his motion rather slowly.

Discharged Oct. 31, 1904.

CASE 41. J. S., male, twenty-nine, married. Operation, July 11, 1904.

Large sessile tumor found in quadriceps pouch above condyles of femur. A few small lipomata also present.

Rapid convalescence and return of function.

CASE 42. F. W. E., male, thirty-three, married. Operation, Aug. 29, 1904.

Very large amount of serous exudate when joint was opened. Upon looking into joint all the serous surfaces were seen to be extremely injected or covered with an exudate which could be easily removed. Directly under the patella was found a lipoma the size of a horse-chestnut projecting into the joint cavity; another was attached to the capsular wall on inner side of the patella. When second incision was made, several small roughened areas were found over outer, lower edge of the patella. These were excised and upon examination found to be areas of rapidly proliferating cartilage.

Eight days later wound entirely healed, except for small area about wick.

July 10, 1905. Knee more swollen than at last visit. Fluid increased.

July 17. Probable fibrous or villous changes in capsule.

Jan. 5, 1906. Can voluntarily hyperextend leg when bearing full weight. Slight lateral mobility. Can voluntarily flex leg to normal.

Jan. 6, 1907. Can flex and extend leg to normal. Lateral mobility when bearing weight. Knee bows outward markedly. Joint much enlarged, and marked crepitation can be felt over entire joint in flexion or extension.

Symptoms of tabes detected for the first time. Evidently a Charcot arthropathy.

CASE 43. F. J. B., male, twenty-five, single. Operation, Nov. 4, 1904.

A much thickened fatty capsule was found which extended well beneath the surface of the patella. This was removed and nothing abnormal found upon examination.

Nov. 21, 1904. Can flex knee only 15°. Motion slowly increased. Discharged.

CASE 44. A. B. R., male, thirty-eight, married. Operation, Jan. 10, 1905.

Four ounces of fluid escaped when joint was opened. Small pannus found near the internal condyle of femur with fatty fringe attached. Both were removed.

Discharged Jan. 24, 1905. Fair immediate result.

March 20. No symptoms referable to joint. Excellent final result.

CASE 45. J. P. S., male, twenty-eight, single. Operation, July 17, 1905.

Numerous fibrous fringes found projecting into joint from the internal lateral ligament, in such a position that they might easily be pinched between the joint surfaces whenever motion was attempted. Over the face of the external tibial condyle was noted a small area, 1.5 cm. in length and 0.7 cm. in width, the site of an inflammatory lesion. The semilunar cartilage presents the appearance of having been fractured. The upper end of a tongue-like process could be caught up with forceps, and although it could be detached, it had produced a roughness on the upper joint surface. Cartilage was not removed.

Pathological report: "Specimen consists of three or four irregular shaped masses of a fatty-fibrous nature which show on the smooth surface a thin covering of synovial membrane. Shining through this surface are numerous fine capillary vessels. Fat is held firmly in lobules. No special vascularity noted in the deeper tissues."

Discharged July 29. Patient has had considerable pain, especially at night. Cast applied to-day and split down both sides; instructions given to wear same at night and flannel bandage during the day. Discharged home.

Aug. 1. Less pain. Instructed to begin walking without cast.

Aug. 9. No subjective symptoms from right knee. Some capsular thickening can be palpated, however. Both knees are capable of hyperextension and some knock-knee deformity is present.

April 3, 1907. Complains of pain in left knee. Functionally right knee is in good condition.

CASE 46. F. J. H., male, thirty. Operation, March 9, 1906.

Several fringes were excised from the anterior joint surface of the left knee, and many smaller tabs were curetted out, care being taken not to injure cartilage any more than possible.

Convalescence rapid and progressive.

Discharged twelve days after operation.

April 4. No symptoms.

CASE 47. H. W., male, twenty-two, single. Operation, Oct. 3, 1906.

Synovia greatly thickened and two large finger-like villous processes removed. A few smaller ones were found which were also excised. No erosions found.

Oct. 12. Patient has 80° of free motion.

Oct. 16. Discharged. Out-Patient record shows no subsequent subjective symptoms.

CASE 48. T. W., male, forty-eight, married. Operation, Feb. 2, 1907.

Slight excess of fluid escaped from joint, external cartilage partially detached and small lipoma adherent to infrapatellar fat pad. Silk wick.

Discharged sixteen days later. Motions nearly normal.

Rapid and progressive return to normal function.

CASE 49. T. C., male, twenty-one, single. Operation, Oct. 21, 1908.

Lipoma found adherent to joint capsule below and to both sides of patellar ligament, 1½ inches by ¾ inch by ¼ inch.

Discharged sixteen days later. Pain and swelling entirely disappeared. Motion to a right angle.

Dec. 23, 1908. Flexion to a right angle. Beyond this point flexion is accompanied by "catching" pain. Massage and baking.

Nov. 5. Ridges felt along inner condyle.

R. K. I., gtts. x, t. i. d., and increase to gtts. xxx, t. i. d.

Nov. 13, 1909. Re-entered hospital. Arthrotomy and small semi-detached piece of cartilage removed from outer femoral condyle.

Dec. 17. Returns to Out-Patient Department. Motion almost to a right angle.

Case 50. A. D., male, twenty-eight, single. Operation, March 10, 1909.

Left knee-joint opened over inner side. Small lipoma found on anterior surface of joint and removed.

March 21. Discharged. Motion to a right angle. Beyond this motion is accompanied by some pain, very little tenderness.

June 28, 1909. Re-entered hospital.

About one month ago began to have pain in left knee. The joint is swollen and tender. Slight atrophy of the thigh and calf. Considerable capsular thickening and slight surface temperature over inner condyle of femur. Question of tuberculosis of soft parts. Plaster cast applied but no relief obtained from symptoms.

July 2. Discovered that patient is addicted to the use of morphine, which is in a large measure held responsible for symptoms.

July 12. Cast removed. No swelling or thickening of capsule. Motions of knee good. Patient still complains of pain. New cast applied with leg in few degrees of flexion.

Discharged.

The detailed description of these cases gives one a fair chance to estimate the success of arthrotomy in this class of patients. As will be seen from a study of the cases subsequently reported, and a comparison with these, there was the greatest number of unfavorable results among this group. There was a higher mortality and more stiff joints, and post-operative manipulations were proportionately more numerous here than elsewhere. The 50 cases belonging to this group show 44 restorations to normal function without infection and without any very protracted convalescence. Six cases were infected. Two of these died. Of the two that died, one was doubtless infected from another case operated upon unadvisedly at the same time and in the same room. The other was a case that had both knees operated upon at the same time, which we now regard as a technical error. The four other septic cases were not explained except in one case, and this now has a normal joint. This should not be classed strictly as sepsis for the joint was scalded by water used to check synovial hemorrhage and the larger part of the synovial membrane sloughed out. One of the cases, a double one, also operated at one sitting, lost her leg above the knee. There is a good deal of evidence that this was a syphilitic subject, but this is not offered in extenuation of the results. If it was, it was just as much an error to have operated it as it was to have infected it. A better showing might be made if the double cases were counted as separate operations, but they have not been so counted. We regard it a serious error to do both knees at one sitting.

The next largest group of cases for which arthrotomies have been performed at this clinic has been that in which the removal of tuberculous disease has been undertaken, and a little space will now be devoted to a consideration of the technic of the two procedures by which this is ordinarily accomplished, viz., excision and erasion.

Technic of the Operations for Excision and Erasion of the Knee-Joint.

The patient is subjected, twenty-four hours previous to the operation, to the routine preparation as before described.

Strict aseptic precautions are used in the final preparation of the patient in the operating room. A tourniquet should then be applied at about the junction of the middle and upper thirds of the thigh. The classic U-shaped incision is employed with the base just above the tibial tubercle and the arms extending up either side of the knee-joint to points opposite the top of the quadriceps bursa. The patellar tendon is next encountered and cut directly across just below its mid point. The capsule is then incised, and while an assistant grasps the upper end of the severed tendon with a tenaculum and retracts the flap, at the same time gently flexing the knee, all intervening tissue and adhesions are cut by the operator, including the crucial ligaments, if they are not already destroyed by disease. The leg is eventually flexed to about 130°. The joint should then be thoroughly inspected; all diseased synovia should be dissected off. Next the tibial and femoral condyles are inspected and the amount which it is desirable to remove determined upon. Careful section is then made (care being taken to have all contiguous soft parts dissected away), slanting the saw about 5° in order to have the joint in the position of slight flexion.

The head of the tibia is then removed. After this procedure all diseased tissue in posterior portion of the joint should be removed, both bony surfaces and all contiguous tissue swabbed with tincture of iodine. The leg is then extended and the bony surfaces approximated. Three or more chromic catgut sutures may be used to hold the bones in place. A bone drill is employed. Beginning about half an inch below upper surface of tibia, in median line the drill is directed upwards so that it comes through the tibia about one inch from the anterior margin of the cut surface. Two similar holes are made on either side and about one inch distant from the original. The femur is treated in the same manner. The bony surfaces may then be approximated by the assistant and the sutures tied. The assistant has no further duty except to hold these two bony surfaces in close juxtaposition. Any sinus which may be present in the tissues should be thoroughly curetted or dissected out entirely. Several interrupted catgut sutures are used to bring together the capsule of the joint. A semilunar

portion of flap may be removed and also the patella at the discretion of the operator. The fascia is then brought together with catgut sutures and the patellar tendon is united with three layers of silk or chromicized gut. Skin is closed with interrupted silkworm gut. A wick may be left in either angle of the incision for twenty-four hours. Dry dressing and bandage. Plaster of Paris bandages applied from foot to groin and carefully modelled while the limb is held with great care.

POST-OPERATIVE TREATMENT.

Unless pain and temperature contra-indicate, it is not necessary to examine the wound until the tenth or twelfth day. A large window cut in the cast enables one to make this examination, exposing the entire upper surface of the knee. If a wick has been used it should be removed on from the second to the fourth day.

At the end of second week the patient may sit up. The cast should be changed at the end of the fourth week. Union is usually fairly firm at this time.

Patient may use crutches during sixth week and bear weight at end of eighth week. Cast may generally be removed about the twelfth week. A leather cast may be used for a time after this if necessary, but is not generally required. In some cases a posterior wire splint is indicated immediately after the operation for two to three weeks, after which a cast may be put on for the remainder of the convalescence. The use of wire sutures is not generally desirable because of the frequency of necrosis about them. Of late some operators are attempting to hold the bones for a few weeks by plates similar to those employed by Lane in the open treatment of fractures. Occasionally wire nails are driven up from below through the tibia into the remains of the femoral condyles. Failure to unite after the usual time has always meant, in our experience, that all the disease was not removed and a fresh focus had started up along the line of union of the two bones. Two such cases are among those reported here. In both cases union took place promptly after the secondary operation, and in both cases there was tuberculous tissue lying in between the two bones.

EXCISIONS.

(Male Cases.)

CASE 51. T. M., male, forty-six, married. Operation, April 11, 1902.

Knee-joint excised for deformity after old tuberculosis.

Firm fibrous adhesion present. No active disease. Silver wire used to hold bones in apposition. Leg put up in posterior wire splint.

May 14. Normal convalescence. Cast removed and new one applied. Discharged.

June 20. Silver wires removed. About a dram of pus evacuated from pocket near the twisted ends of the outer wire.

July 6. Discharged well.

CASE 52. R. M., male, fifteen, single. Operation, Sept. 3, 1902.

Diagnosis: Infantile paralysis with ankylosis of knee.

Attempt made to forcibly correct the knee under anesthesia unsuccessful owing to contracture of hamstrings and posterior capsule. After the usual incision was made and joint exposed, the knee was forcibly flexed and firm adhesions broken. One inch of lower end of femur removed and posterior capsule incised before bone surfaces could be approximated without putting too much tension on popliteal vessels and nerve.

Sept. 11. Wound became septic immediately after operation. Staphylococcus aureus.

Oct. 18. Wound nearly healed. Leg in position of slight genu valgum.

Oct. 20. Discharged.

Dec. 19. Patient wearing split plaster cast. Position slightly improved.

Jan. 16, 1903. High sole advised.

Feb. 13. Patient instructed to leave off wearing cast gradually and begin to bear weight upon the foot.

CASE 53. A. D., male, eighteen, single. Operation, March 12, 1903.

Excision of knee. Infantile paralysis.

On April 27, 1903, hamstrings were cut, but complete extension could not be obtained. Patella and surrounding capsular tissues removed. Wedge-shaped piece of bone removed from lower end of femur to correct deformity. Excised bony surfaces approximated and heavy silk sutures used to hold same in place, being passed through periosteum of each bone.

May 25. Discharged. Recovery uneventful.

Oct. 29, 1903. Wearing brace with comfort. No further history.

CASE 54. T. E. S., male, eighteen, single. Operation, April 8, 1903.

Old focus of disease found in middle of articular surface of internal tibial condyle. The core, a solid necrotic mass, was removed as a whole, exposing a sound cavity 1 cm. in diameter with necrotic walls. Anterior surface of apposing femoral condyle eroded and an infiltration of the surrounding tissue. Patella, bursæ about joint, and surrounding soft parts removed. Silk sutures used to hold bony surfaces in apposition.

April 28. Wound healed. No pain or discomfort.

May 5. General condition improved. Patient can bear weight on leg without pain.

May 7. Discharged wearing new cast.

CASE 55. T. S., male, twenty-nine, single. Operation, Oct. 6, 1903.

Joint surface studded with tubercles. External condyle of femur eroded and cavity found in opposite condyle of tibia without sequestrum.

Oct. 27. Tubercule bacilli found in sputum.

Nov. 10. Discharged. Knee condition good. General condition poor. Patient died a few months later of tuberculosis (general)?

CASE 56. D. L., male, twenty, single. Operation, March 9, 1904.

Few adhesions found in joint. No pus. Pannus over condylar cartilage and slight erosion of bone at margin of cartilage. Crucial ligament pulpy and hemorrhagic. Focus in external tibial condyle.

March 10. Patient had some hemorrhage from knee, which was finally controlled by pressure.

March 30. Wound healed. New cast applied.

April 10. Discharged. Excellent result as to function and position.

CASE 57. J. P., male, fifty-five, married. Operation, June 24, 1904.

Considerable hemorrhage at the time of operation and for fourteen hours following. Finally controlled by compresses and elevation of the leg.

June 29. Considerable ooze when wicks were removed.

July 15. Discharged. Healing delayed owing to poor general condition of patient.

Nov. 20, 1905. Union has not been complete, due probably to a fibrous pannus between excised bones, allowing small amount of flexion. Refused operation. Leather cast.

Case 58. T. M. K., male. Operation, Oct. 21, 1904.

Considerable osteoporotic bone curetted out of both condyles of femur and tibia. Operation not unusual otherwise.

Discharged Nov. 23, 1904. No further history obtainable.

Case 59. T. M., male, seventeen, single. Operation, June 14, 1905.

Patella found ankylosed and had to be pried off with chisel. Very firm ankylosis of joint in poor position. Synovial capsule entirely obliterated. Owing to the subluxation of the tibia a wedge-shaped slice of bone thicker than normal had to be removed from the femur. No evidence of active disease found in joint or bone.

June 30. Wound clean. Stitches removed and new cast applied. Good operative result.

Patient died of general tuberculosis several months later.

Case 60. F. B. E., male, twenty, single. Operation, July 24, 1905.

Some tubercular pus found. Joint cavity very small owing to the encroachment of fibrous tissue. Exuberant granulations over internal condyle of femur and up into quadriceps pouch, including that portion of the patella which rides over this area. The internal condylar notch shows extensive tubercular granulations. In the external femoral condyle is a sulcus dividing that surface into separate areas, and it is possible to separate remaining cartilage only with difficulty. The tibia seems remarkably free from involvement in the process. The patella was removed with its adjoining capsule. Most of the granulations were in a state of fatty degeneration. The quadriceps pouch was not as extensively involved as usual and could be dissected out *en masse*. No deep-seated foci were found. The disease was evidently primarily a synovial affair now just beginning to encroach upon the bone. Excision was done owing to the fact that a satisfactory result in motion would not be likely after a simple erasion.

Aug. 13, 1905. Discharged wearing cast.

June 11, 1906. Patient has had leg in cast since above note. Union is imperfect and seems unlikely to be accomplished.

Operation June 12, 1906.

Same incision used and fibrous pannus found across upper surface of tibia with two small foci underneath, each containing a small amount of tubercular pus. Bony surfaces freshened and approximated with kangaroo tendon.

Discharged June 25, 1906.

Six months later examination of patient showed most excellent post-operative result. Patient has had no return of symptoms to present time.

Case 61. A. D., male, twenty-eight, married. Operation, March 30, 1906.

This case was diagnosed as a possible villous arthritis. Linear incision made over outer anterior surface of knee. Considerable villous thickening present. As much as possible of this was removed and sent for pathological examination, the result of which was a diagnosis of tubercular synovitis.

Discharged April 10, 1906.

On April 26, 1907, patient re-entered hospital suffering from an exacerbation of all previous symptoms. Upon examination of the joint swelling, surface temperature and obliteration of all fossæ normally present about the joint was noted. An excision was deemed advisable, but was delayed for three weeks. The lower end of the femur and upper end of the fibula appeared normal. Slight pannus formation noted over almost entire head of tibia. A thick, red, edematous membrane was found enveloping the patella and occupying the quadriceps pouch. The crucial ligaments were involved to an unusual extent, and there was thick gelatinous material extending down to the head of the tibia. Patella unusually large, but not diseased, though it was resected.

Excision of both bones performed and convalescence uneventful.

Discharged May 16, 1907.

No recurrence of symptoms, except a small discharging sinus, up to Aug. 22, 1908, when patient again entered hospital.

A marked tenderness had been gradually developing at the site of the healed sinus at a level with and corresponding to the old joint. Pain pronounced only when standing, which was gradually increased in intensity and duration. Right leg, 2 cm. shorter than left. Right thigh shows 5 cm. atrophy. A compensatory scoliosis of spine present.

Operation Aug. 26, 1908. A 2½-inch linear incision was made on inner side of patellar tendon down to bone. Periosteum dissected back and focus of necrotic bone found in tibia just under the last discharging sinus and at level of previous joint. Same curetted out and tincture iodine applied.

Sept. 3. Patient has had no discomfort from knee since operation. Discharged home.

Nov. 24. Knee has been tender and some pain has been experienced since last operation. X-ray shows evidence of active disease between excised bony surfaces. Patient again re-entered hospital. General condition improved. Former excision exposed through U-shaped incision. An opening was found between the two bones communicating with a cavity in the femur. Similar focus in head of tibia and tubercular tissue found between bones. The parts were cleaned out thoroughly and bones again approximated.

Discharged wearing plaster of Paris cast, Nov. 30, 1908. No recurrence of symptoms to date of writing, 1910. Union solid.

Case 62. G. D., male, twenty-two. Operation, April 13, 1906.

Flow of tubercular pus when joint was opened. Disease limited to synovial membrane, external condyle of femur and quadriceps pouch. The latter was walled off except for small sinus connecting with the joint proper. Recovery uneventful and patient was discharged April 29, 1906.

Three months later physical examination shows no motion at knee-joint. No pain has been experienced and patient was, therefore, instructed to begin bearing weight.

Feb. 11, 1907. Small fluctuating area found over anterior junction of tibia and femur.

℞ X-ray. No subsequent history; x-ray not found.

Case 63. W. M., male, twenty-three, single. Operation, Nov. 21, 1906.

Synovia pale and redundant; process general but of low-grade virulence. Pulmonary symptoms delayed convalescence.

Discharged Dec. 14, 1906. Advised general hygienic treatment.

Pulmonary tuberculosis. Further history not obtained.

Case 64. P. L., male twenty-nine, single. Possibly Charcot joint (?). Operation, Nov. 21, 1906.

Right knee opened over inner aspect. Just beneath skin a cystic cavity not communicating with joint was found, which was formed of redundant fat and fibrous tissue. Joint opened and a small amount of bloody fluid escaped. Internal condyle thickened, friable and

covered with tubercular-like granulations. Practically entire condyle removed and wound closed.

Dec. 10. Plaster cast applied.

Dec. 12. Discharged.

Dec. 31. Knee in good position. Split plaster and begin weight-bearing.

Feb. 17, 1907. Complains of discomfort over outer surface of knee. X-ray shows exostosis of tibia and femur. Re-entered hospital.

Feb. 18. Operation. Knee-joint opened over outer side. Cartilage and synovial membranes thickened and congested. When knee was flexed, condyles were exposed and presented a marked hypertrophic condition. Both ridges removed. Bone and cartilage soft. Wound closed.

Feb. 28. Discharged.

March 3. Patient wearing plaster cast. Slight swelling over outer surface of knee and some pain in right ankle-joint.

June 12, 1907. Considerable thickening about condyles.

CASE 65. M. M., male, eighteen, single. Operation, Jan. 21, 1907.

Linear incision over outer surface of knee. Synovial membrane found injected and thickened. A portion of this was removed. Also one fringe 5 cm. by 1½ cm. and sent for pathological examination. Bone apparently normal according to x-ray and actual finding.

Jan. 26. Persistent pain in knee-joint.

Feb. 11. Septic stitch delayed healing of wound.

Feb. 13. No improvement in motion of joint. Pain very acute with attempted flexion.

Feb. 18. Under chloroform leg forcibly flexed to a right angle with hardly any resistance.

Feb. 21. Forcible flexion accompanied by extreme pain.

Feb. 25. Can flex almost to a right angle. Extension limited to within 10° of straight. Delayed pathological report. Tubercular synovitis.

Feb. 27. Leg put in plaster of Paris bandages. Tonic treatment to improve general condition. Discharged home.

Readmitted Oct. 2, 1907. Patient has been wearing plaster of Paris cast since Febuary. Knee swollen and very painful without cast.

Oct. 23. Excision performed. Bone somewhat osteoporotic.

Nov. 12. Convalescence uneventful. Discharged home.

Dec. 6, 1909. No symptoms for past two years. Excellent result.

CASE 66. J. H. M., male, eighteen, single. Operation, Dec. 30, 1908.

Quadriceps pouch of right knee adherent but not markedly infiltrated. Numerous eroded areas were found over internal condyle of femur and corresponding upper surface of the tibia, with only a few small islands of cartilage remaining. Many of the erosions were deep. There was a distinct fibrous envelope isolating this region from the rest of the joint. When incised about 2 oz. of sero-sanguinotal fluid escaped. The outer trochanter of the femur and opposite surface of the tibia practically normal and very little extension of synovial disease in this direction. One crucial ligament was considerably disintegrated. On the posterior surface of the internal condyle a soft area of bone was found. This was curetted out to depth of ¾ inch. The semifluid substance expressed resembled pus, but may have been fat.

Jan. 13, 1909. Discharged home wearing cast.

Feb. 15. Wound entirely healed. Knee is in position of slight hyperextension. New cast applied.

March 29. Knee in good condition.

Dec. 1. Patient still wearing cast. Has had some pain when cast was split, but condition now is improved. To leave off cast gradually. Massage to thigh and calf.

CASE 67. J. St. J., male, seventeen, single. Operation January, 1909.

No joint cartilage remaining. Considerable healed tubercular tissue removed. Wick put in either angle of wound and leg put up in plaster of Paris. There was considerable ooze from the wound for twelve hours following operation.

Feb. 8. Wick removed.

Feb. 15. Wound septic about inner angle when wick was removed.

Feb. 24. Septic infection readily yielded to treatment. Cast changed.

Feb. 26. Window cut over small granulating area. Slight discharge.

March 8. Discharged home. Leg in 15° permanent flexion.

Jan. 1, 1910. No exacerbation of disease and fair result as to position.

CASE 68. V. R., male, thirty-seven, married. Operation, April 14, 1909.

Left knee-joint excised. Greater part of joint cavity contained healed tubercular tissue. One small focus in head of tibia; otherwise the bone not deeply involved.

April 16. Considerable ooze from joint for twelve hours following operation. No pain or other symptoms to note.

April 28. Renew cast.

May 3. Discharged.

Nov. 12, 1909. Still wearing cast. No subjective symptoms. Excellent result.

CASE 69. U. B.

Both articular surfaces diseased, and there was considerable involvement of the soft parts. Two small foci found in femoral head. In tibial head was a focus which apparently penetrated bone to soft parts.

Dec. 23. No post-operative symptoms. Patient discharged wearing plaster cast.

(To be continued.)

Clinical Department.

THE EXTREME BLOOD PICTURE IN A CASE OF PERNICIOUS ANEMIA.

BY W. C. SPEIDEL, A.B., M.D.,
House Physician, Cook County Hospital, Chicago, Ill.

THE following case is deemed worthy of report on account of the remarkable degree of oligocythemia presenting, the red blood cell count, dropping to 100,000 per cubic millimeter two hours before death, being the lowest count yet reported. The hemoglobin at that time as nearly as could be calculated was 9% (Sahli).

In the literature on the subject of pernicious anemia, Cabot mentions two cases in which the count fell below 200,000, citing the celebrated case of Quincke, 1877, of 143,000, and referring to two other cases. Hills, 1898, reports 155,280; Naegeli, 1908, 138,000, reports the lowest up to that time. This indeed is noteworthy when one considers that in the extensive and voluminous amount that has been written on this subject, a count of 1,000,000 is frequent; so low as 500,000, uncommon; below that number, rare, and when it is called to our attention that a count of less

than 200,000 is reported in but four cases, it becomes of exceeding interest to learn if possible what might cause or bring about such extreme poverty of the blood. If unexplainable upon the basis of the facts in the case, it is of speculative interest, to say the least.

Before introducing the case it might be well to make in brief a few remarks in regard to the pathogenesis of the condition. The researches of Bunting, who produced experimentally in animals a gradually long-standing hemolysis by the injection of small doses of ricin, proved that a typical megaloblastic metamorphosis of the bone narrow can thus be produced, a metamorphosis identical with that seen in pernicious anemia. With larger doses of this or other hemolytic agents we get, as after experimental exsanguination, a red marrow, whose color is due not to megaloblasts, but to normoblasts and normal red cells. Bunting suggests the interesting hypothesis that in pernicious anemia we are dealing with a hemolytic process produced by a poison which exerts its action over a considerable time; that in an attempt to repair the damage done by this poison, the peripheral layers of the germinal erythrogenetic centers are first "peeled off" as in ordinary secondary anemia. Then, as the new formed erythrocytes are rapidly discharged into the blood with the continuation of the hemolytic process and the prolonged stimulation and acceleration of the blood-forming activities, the germ centers where the large immature red corpuscles lie become enlarged, over-active and finally crowd out all the other tissues of the marrow, so that immature red cells, often nucleated and of the large type characteristic of the erythrogenetic centers, are discharged into the blood in an unsuccessful attempt to make up for the losses due to hemolysis.

Cabot further says that if, as in cases of anemia due to the fish tapeworm, we can remove the source of blood destruction, the marrow returns to its normal condition, functions in the normal way and the patient recovers. If, on the other hand, as in cryptogenetic anemia, the hemolytic agent cannot be found or removed, the marrow grows more and more bankrupt.

William Hunter holds that the hemolysis which is now generally considered responsible for the disease is of gastro-intestinal origin, citing as evidence an increase in amount of iron pigment normally deposited in the liver and, to a lesser extent, in the spleen. It has been shown, however, that when hemolytic agents are introduced through the blood stream itself, these iron deposits occur in the same way as in pernicious anemia of the ordinary type. It seems more likely, as is generally assumed, that the unknown poison of pernicious anemia stimulates and pathologically exaggerates the normal phagocytic and hemolytic activities of the spleen, lymph glands and marrow. The pigment in the phagocytic cells and stroma of these tissues fails to give the iron reaction. It is in the liver and kidneys that it is changed to hemosiderin, but the primary destructive agencies are in all probability in the hemopoietic organs themselves.

History of case. — Patient, R. G., male, forty years of age, nativity Ireland, has been in this country twenty-two years; is married.

Admitted to Cook County Hospital Feb. 8, 1910, on the service of Drs. Loeb and Mix.

Present complaint. — General weakness, some cough and vomiting. The onset was insidious and indefinite and is dated as beginning about one year ago with soft chancres, following which patient began to lose weight, noticing pallor and progressive weakness and shortness of breath, and "night sweats" were frequent. Several attacks of vomiting during that time; these attacks were unaccompanied by pain, bear no relation to eating. No hematemesis or blood in stool. Coughing has been persistent for the past five months, no hemoptysis, expectorates considerable greenish-yellow sputum.

Previous diseases. — Had muscular rheumatism one year ago, gonorrhoea eighteen years ago, for the past ten years has had urethral stricture, some difficulty in urination and has frequently had urethra dilated. Had a chancre fifteen years ago followed shortly by secondary eruptions. Has since had children who were strong and show no hereditary taint.

Habits. — Has been a "hard drinker" for years. Present occupation a motor-man, formerly a butcher.

Family. — Parents died of old age; two brothers and three sisters living. Wife is living and well. Has living children. There is no history of similar disease in the family.

Physical examination. — General: Shows a poorly nourished, pale, somewhat lemon-tinted, white male about forty years of age, of uncertain gait, good mentality, complaining of general weakness and some numbness of the extremities.

Regional. — Head and neck: Pupils unequal, left smaller than the right, react very sluggishly to both light and accommodation. Tongue is pale and flabby, as is mucous lining of mouth in general. Teeth are poor (pyorrhea alveolaris). Cervical glands are not enlarged.

Chest: Prominence of right clavicle. Lungs: Some râles and impaired resonance over upper right lobe; also roughened breathing in the same region. Heart shows normal area of dullness, no irregularity, a hemic murmur at the base; second sounds are unaccentuated. Abdomen: Spleen and kidneys are not palpable. Liver extends one finger's breadth below the costal margin and is not irregular or tender. No ascites or palpable tumor masses. Inguinal glands palpable but not enlarged. Rectal examination is negative. Genitalia and lower extremities are negative.

Nervous system: Left patellar reflex absent, right reduced. Babinski positive on both sides. No girdle sensation, no acute gastric or shooting pains and no bladder trouble except as could be accounted for by stricture of urethra. Muscle and joint sense gone. Rhomberg positive and gait is noticeably of stamping quality. Numbness and tingling sensation are complained of in the lower extremities.

Functional irritability and some inability to fix attention are present; insomnia has been bothersome at times. Memory is good.

Subsequent history. — The course of the disease from then until the end, thirty-two days after entering hospital, is with but a slight suggestion of remission, progressively downward, and of chief interest are the blood findings. Other points less noteworthy are merely to be mentioned in passing.

Feb. 10, two days after admission, blood examination shows: Hemoglobin, 36% (Sahli); red blood corpuscles, 1,566,000; white blood corpuscles, 4,800; color index, 1, plus.

Feb. 25, hemoglobin, 19% (Sahli); red blood corpuscles, 680,000, showing a drop of over a half million in fifteen days; white blood corpuscles, 4,000; color index, 1, plus.

Differential white cell count (100 cells) show polymorphonuclear neutrophiles, 61%; lymphocytes (large and small), 32%; transitional, 2%; neutrophilic myelocytes, 3%; eosinophiles, 1%; basophiles, 1%.

During the differential count eight nucleated red cells were seen, four of which were normoblasts, and an equal number of megaloblasts were present. Marked chromatophilia and a tendency toward macrocytosis is noted. Poikilocytosis is not marked; no blood platelets found.

March 5, hemoglobin, 14% (Sahli); red blood corpuscles, 750,000; white blood corpuscles, 4,200; color index, $\frac{14}{19}$, slightly less than 1, showing if anything a slight degree of improvement in the blood condition over that noted a week previous. In a stained smear at this time one megaloblast only appeared in the field in one of three slides. Both poikilocytosis and polychromatophilia are marked. No normoblasts are found.

March 10, hemoglobin, 12% (Sahli); red blood corpuscles, 780,000; white blood corpuscles, 2,200; color index, $1\frac{2}{3}$ approximately, is still less than 1. Here is noted only a small increase in the red cells. The white cells are notably diminished in number and the hemoglobin also on the decrease. Eight to twelve megaloblasts were found on a single slide and four to six normoblasts.

March 12, two hours before death, the final count shows the most interesting changes above mentioned, namely, (1) Hemoglobin, 9%. It is found that Tallquist and the Dare instruments do not register; however, using two volumes of blood where one is called for, with Sahli hemoglobinometer then registering 18%, dividing by 2 for correction, the above result obtains. The instrument is six months old and the acid hematin control has probably not deteriorated. It is possible that the hemoglobin content here is less than 9%, for it must be borne in mind that from deterioration, improper standardization and the age of the individual arise sources of error which must be taken into account before absolute calculation can be made. Webster reports an error of 25% arising from faulty standardization of Sahli's solution. However, a discrepancy in favor of a higher color count is tenable on the same grounds, though inapplicable here, I think. Naegeli mentions as the lower limits in extreme cases, 12, 10, 8, and even 7% hemoglobin.

(2) Red blood corpsucle, 100,000 per cmm. A free drop from the lobe of the ear was obtained with some difficulty owing to the remarkable degree of oligocythemia existing, necessitating a liberal stab. A second drop was taken, a new stab being made in order to obviate possibility of error and for a check and control, Hayem's solution, fresh and recently filtered and in the dilution of 1: 100 being used, Thoma-Zeiss counting chamber counting 200 squares, in each case recounting each a second time to avoid possible inaccuracy. An even distribution was noted and microcytes were included in the counting. (Emerson has noted an error of 200,000 arising from overlooking this form of cell.)

(3) White blood Corpuscle, 2,400, an inconsiderable increase over that of the forty-eight hours preceding.

Differential white count of 100 cells at this time shows

	Per cent.
Polymorphonuclear leucocytes,	56
Lymphocytes:	
Small,	28
Large,	11
Transitional,	1
Neutrophilic myelocytes,	4
Eosinophiles,	0
Basophiles,	0

During the count ten normoblasts, twelve megaloblasts and five intermediates, including the latter with the megaloblasts, give a Von Noorden blood crisis, of megaloblastic type, of 170 per 1,000 leucocytes, — the arbitrary lower limit being taken as 50 per mille. It is here seen that myelocytes were thrown out into the blood at this time. In a crisis of this sort eosinophiles should rise; in looking over the slide none are found; a jump in the red count is usually concomitant or follows shortly. Such was not evident in the present case and serves to illustrate the variability within certain limits of the blood picture of pernicious anemia relative to this point. Emerson, reporting 89 cases, in 20 finds an increase in the number of red cells counted within forty-eight hours preagonal, occurring quite uniformily, making note of interest in the fact that the higher the count with the first symptoms, the higher it is at death. How, then, in the face of such evidence, is such extreme paucity of red cells to be explained, unless we assume that the hemolytic agent causing this destruction was especially and intensely toxic at this period of beginning dissolution or, on the other hand, that vasomotor paresis is paramount in producing a relative local anemia or ischemia, considerations which at best must be purely hypothetical?

Skelton-Barlow stain used throughout.

(4) Color index, 4.5. This is exceedingly high, though hyperchromemia, as we know, is one of the characteristics of the disease. The volume index in this case unfortunately was not taken, but through the kindness of Dr. Capps, who measured 100 cells, we found an average diameter of 8.1 microns (7.5 microns normal), which leaves some discrepancy as to the high color proportional to the size of the individual cell. Capps has shown and upholds the theory that the color index is never increased without corresponding or greater rise in volume index; that it is not due to an increased affinity of cell protoplasm for hemoglobin. And furthermore, this fact proven, it is quite unnecessary to assume a supersaturation of the cell with hemoglobin. Another source of error is suggested by Emerson, who says, "The high color index of pernicious anemia has perhaps with reason been attributed to the fact that microcytes are overlooked." As previously stated, such I think is not the case here. Here applies also what was mentioned under hemoglobin estimation above with regard to source of error relative to defective instrument and so forth.

(5) The drop is pale, watery appearance, showing fluidity especially, and the halo about the drop so often described and rarely found in other diseases according to Cabot. Absence of rouleau formation is noted, as is also delayed coagulation time.

Coma supervened before death, six hours.

Diagnosis. — An autopsy was refused. It is, therefore, impossible to determine anything definite as to actually existing pathology underlying; however, the clinical picture is such that the diagnosis of pernicious anemia seems justifiable on those grounds alone, fulfilling many if not all the requirements suggested by Billings, namely, "when we find a marked oligocythemia, with the presence of many poikilocytes, microcytes and macrocytes, with polychromatophilia, and a

relatively high percentage of hemoglobin with normal or higher than normal color index, it affords a type of blood which is found in no other anemic state. If to this we add the presence of nucleated red cells, and especially of megaloblastic type of red cells and a few myelocytes, which together indicate degeneration of bone marrow, the diagnosis is reasonably certain without post-mortem examination.

As to type, it is of cryptogenetic origin, the idiopathic form called Addison's anemia by Hunter, in that it conforms fittingly to the negative findings, which were emphasized by Addison so early as 1855, namely, cases where there had been no previous loss of blood (in this case slight and occasional epistaxis is noted), no exhaust-diarrhea, no chlorosis, no purpura, no renal, no splenic, no miasmatic, glandular, strumous or malignant disease.

Ophthalmoscopic examination showed slight hemorrhage into left retina. Urine showed small amount of albumin and an occasional cast, no edema of the extremities or puffy eyelids. Repeated stomach, sputum, and examination of the stools showed neither malignancy, tubercle bacilli or animal parasites. Diminished acidity of stomach contents was noted. No evidence of hemorrhoids or other cause of secondary anemia except slight nose bleed.

The diagnosis of tabes dorsalis is hardly tenable, and, if entertained, must be so on the assumption of a superimposition. Clinical evidence of dorsal column involvement is insistent, sphincter disturbance is absent, as is also a history of crises of any sort, and, in the presence of additional lateral cord involvement, as evidenced by a double Babinski, speaks for a combined cord degeneration due in all probability to the common hemolytic agent which is responsible for the most damaging and terminally destructive changes in the blood.

Medical Progress.

PROGRESS IN THE THEORY AND PRACTICE OF MEDICINE. GASTRIC AND DUODENAL ULCER.

BY FRANCIS W. PALFREY, M.D., BOSTON.

[Concluded from No. 16, p. 619.]

DIAGNOSIS.

In diagnosis also the influence of surgical evidence has been of great importance. The writings of surgeons, notably those of Moynihan, of Mayo and his associates, of Deaver, of Codman, of Hall, and of a number of reporters from German clinics, presenting large series of cases where the diagnoses were tested by operative findings, have given a far firmer basis for clinical diagnosis than ever before existed. In the light of these findings many discussions have appeared of the significance and diagnostic value of symptoms, of signs and of clinical laboratory tests. As compared with similar discussions in recently previous years there is a notable tendency to lay greater stress upon clinical history and symptoms and to place less reliance upon the findings of the laboratory in the diagnosis of gastric and of duodenal ulcer. Particularly is this true in the case of articles upon duodenal ulcer which from its recent recognition as a common disorder has received the attention due to a new disease. Its symptomatology, in the practice of those who have had the most intimate experience with it, is described by Moynihan [1] as so definite that the history is in itself sufficient for practical diagnosis, rendering other diagnostic evidence superfluous. While this statement must be regarded as an exaggeration, it is undoubtedly true that clinicians at large do not sufficiently appreciate the significance of histories such as are given by the class of patients in whom duodenal ulcers are being demonstrated. A digest of a few of the more important discussions of the symptomatology of duodenal ulcer may, therefore, be profitable in attaching a new significance to a clinical picture which has frequently in the past been denied adequate attention.

Mayo [2] enumerates the symptoms of gastric and duodenal ulcer in common as follows: (1) Acidity — the regurgitation of acid food and of acid-burning contents from the stomach not containing food; this acid regurgitation from the fasting stomach he regards as almost pathognomonic of ulcer. (2) Pain — seldom absent; described as burning or deep boring in character, temporarily eased by food, but as the patient clearly recognizes, later aggravated in consequence of food taken. (3) Hemorrhage — not a frequent symptom, even occult blood in the stools being rare in comparison to its constant presence in cancer. The presence of blood in the stomach contents or stools must always be suspected of coming from other sources. Single large hemorrhages are more often due to other causes (e. g., cirrhosis) than to ulcer. (4) Vomiting — not frequent on account of the care exercised in eating. (5) Gas — a nearly constant symptom. The

symptoms of chronic perforation and of obstruction are also described. The presence of tumor is mentioned as occasionally observed. The distinction between gastric and duodenal ulcer is usually possible, based upon the location of the pain to the left in gastric and to the right in duodenal ulcers, and upon the fact that in the latter its onset is delayed for several hours after eating.

Moynihan,[1] writing of duodenal ulcer, maintains that in recurrent attacks the diagnosis can be made with certainty upon history alone. He lays stress upon the long duration of cases at present seen, and of their remittent and recurrent course, upon the frequent complaint of pain occurring two hours or more after eating and continuing until the next meal, the so-called "hunger-pain," occurring in many instances at regular hours in the day or night, as at 4 P.M., or at 2 A.M. It is often preceded by burning or gnawing sensations, with some belching and bitter or sour regurgitation. The pain, if severe, may be relieved by pressure; in this case it may be due to a spasm of the pylorus such as is sometimes seen at operation. Appetite is usually good and vomiting is rare. Hemorrhage is regarded as a complication rather than as a symptom. Occult bleeding is regarded as of possible diagnostic value, but Moynihan has not made use of it, in confidence in the adequacy of diagnosis from symptomatology.

Deaver,[46] also dealing with duodenal ulcer, attaches chief importance to pain in relation to food. In gastric ulcer the pain may not be immediate, and may even occur in the fasting contents under the influence of hypersecretion, but its constant appearance after a regular and considerable interval after eating speaks for duodenal ulcer. There may be tenderness. The pain is increased by acid and relieved by alkali, and if vomiting occurs, it gives relief. The periodicity of attacks is striking; Deaver believes that cessation of symptoms in the interval between attacks is not to be regarded as temporary healing, but merely subsidence of secondary inflammation.

Codman[3] emphasizes the probable frequent occurrence of non-classical unrecognized duodenal ulcer. He reports the finding by the Pathological Department of the Massachusetts General Hospital of 30 active duodenal ulcers in 2,390 successive autopsy cases dying from all causes, or over 1%. The failure of demonstration of scars of healed ulcers he explains by the probability which he establishes that healing occurs in ulcers of the duodenum without demonstrable macroscopic scar.

Thus all these authors, and others, agree in regarding the history as sufficient basis in itself for a provisional diagnosis, and with such confidence that they are willing in cases which do not yield readily to medical treatment to make this diagnosis the ground for exploratory laparotomy.

Hall,[47] and Graham,[48] from the Mayo clinic, have written in similar vein concerning gastric ulcer. In an analysis of 50 cases of gastric ulcer proved by operation, Hall reports the following occurrence of symptoms: Pain in 82%; sour stomach in 80%; tenderness in 70%; vomiting in 60%; rigidity in 60%; and hemorrhage in but 34%.

It is undoubtedly true, as these authors suggest, that many cases passed as hyperacidity and nervous dyspepsia are in reality cases of gastric or duodenal ulcer.

Of special tests and diagnostic methods there have been few publications that require description. Perhaps the most noteworthy of these is the procedure of Bönniger,[49] which, however, has not yet received confirmation by other authors. Bönniger tests the sensitiveness of the stomach by introducing in the morning after first washing with water, 100 to 200 ccm. of decinormal hydrochloric acid. In cases of ulcer there is immediate intense pain, which is at once relieved by the introduction of milk. If there is no such pain, Bönniger feels that ulcer can be excluded.

Grandauer[34] has written to emphasize the importance of hypersecretion. He has also attaches significance to microscopic stagnation,[50] tested by giving bismuth in the evening and examining for it the washings of the stomach after removal of a test breakfast given the following morning. Recovery of considerable amounts of bismuth, according to Grandauer, occurs only in ulcer and in severe catarrh; if catarrh can be excluded, then ulcer is present. Borgbjärg[51] also supports these conclusions, finding that microscopic stasis is strong evidence for organic stomach trouble — either ulcer, cancer or chronic gastritis; that hypersecretion alone is suggestive of ulcer; and that if stasis and hypersecretion are both present, the diagnosis of ulcer is practically certain.

Einhorn[52] has used an ingenious device by attaching a thread to a small receptacle called a "duodenal bucket" enclosed in a gelatine capsule which is swallowed by the patient and allowed to remain in position over night. In the morning it is withdrawn and in cases of duodenal ulcer a blood stain is said to be found on the thread at a distance from the teeth at which the ulcer is situated. For diagnosis of gastric ulcer a still more complicated procedure is described, — a silk-covered, inflatable balloon at the end of the stomach tube, to be inflated within the stomach, showing a stain on withdrawal opposite the ulcer Ewald,[4] however, reports unfavorably on the use of the duodenal bucket.

Radiographic methods have of late years made great advance in the study of a variety of abdominal conditions, but unfortunately they have failed to demonstrate their utility in the diagnosis of gastric ulcer except in its complications, — pyloric stenosis and hour-glass stomach. Gastroscopy also has been practiced to some extent, but has not yet reached a position of general utility.

Thus the clinical diagnosis of gastric and duodenal ulcer still rests largely upon the time-honored methods of anamnesis and physical examination; but with our added knowledge that gastric and duodenal ulcers are of more frequent occurrence than was formerly believed, their presence is to be recognized or at least suspected on grounds that have hitherto been supposed to warrant only

the diagnosis of hyperacidity or of other disorders purely functional.

PROGNOSIS.

In the prognosis of gastric and duodenal ulcer there have been published no recent statistics of importance except in connection with special methods of treatment with which they will be mentioned later.

A notable fact, however, is the increasing importance attached to gastric ulcer in the etiology of gastric cancer. Rodman[53] has shown this tendency in citing the following opinions as to the percentage of gastric carcinomata which could be traced to previous ulcer; Sonnichsen in 1891, 14%; Klausa in 1900, 26%; Mayo in 1906, 54%; more recently Moynihan, 72%, and Sscapescho, 90%. Hayem,[54] in 94 anatomical specimens of cancer of the stomach, found evidence of pre-existing ulcer in 21. Wilson and MacCarty,[55] however, point out that in investigations based upon post-mortem specimens traces of pre-existing ulcer may be obliterated. In an important communication based upon 210 surgical specimens from the Mayo clinic, they report that of 149 cases of cancer, 109 had definitely developed upon a preceding ulcer, 7 had probably been preceded by ulcer, and but 33 showed no evidence of pre-existing ulcer. Of 52 specimens of ulcer, 5 showed appearances suggesting transition to carcinoma. Jeannel[56] has collected 50 cases, 2 of which are original, where gastric ulcer has produced a gastrocutaneous fistula.

TREATMENT.

With advances in the symptomatology and diagnosis of gastric and duodenal ulcer, and with the great progress in their surgical treatment, new efforts have been made to improve the medical treatment. From 1878 until within the past few years the medical treatment has been based almost exclusively upon the principles of the Ziemsen-Leube method. The requirements of this method as reiterated in a recent article by Von Leube[57] are (1) absolute rest in bed from one to two weeks; (2) ½ liter warm Carlsbad water in the morning on a fasting stomach; (3) hot applications to the epigastrium; (4) restricted diet according to Von Leube's tables,[58] preceded by a few days of absolute fasting with rectal feeding in cases of hemorrhage. Von Leube's diet is divided into four stages. The first, given for the first ten days, includes bouillon, Von Leube's meat solution, milk, and raw and soft-boiled eggs. The second stage diet includes boiled calves' brain, thymus and chicken, gruels and mushes. The third gives, in addition, scraped raw or cooked beef and raw ham. The fourth includes roast meats, boiled fish and macaroni, bouillon with rice and chopped young spinach. A small amount of wine is given before meals. Most vegetables, salads, preserves and fruits are long avoided.

This treatment, however, in its application by other physicians, has been only loosely adhered to. The importance of rest in bed has not been fully realized, and, in the face of objections on the part of the patient, has often not been insisted upon. The use of Carlsbad water, emphasized especially by Ziemsen, has been generally omitted. The use of external applications has not been universal. The diet has been widely varied. The rectal feeding is the part of the treatment which has most often been regarded as the essential measure. This has been very generally employed in cases even without hemorrhage and has often been continued for periods much longer than Von Leube's directions have advised, and undoubtedly by the undue prolongation of this period of scarcely modified starvation much harm has been done. The articles of Von Leube's diet-list have been criticised both upon theoretical and upon practical grounds. A certain proportion of patients do not do well on this diet. The food value of some of its constituents, notably the bouillon, is low, and, according to Pawlow's findings, meat extract and wine are active stimulants to gastric secretion, which is, at least in those cases of gastric ulcer that tend to hyperacidity, distinctly undesirable. Thus most physicians have digressed from Von Leube's diet to a greater or less extent, according to their own experience, and articles upon the diet in gastric ulcer have varied widely in their recommendations.

In recent years much discussion has been aroused by a method of treatment devised by Lenhartz[59] and used by him for eight years with results published at the Congress für Innere Medizin in 1909. This treatment differs from that of Von Leube in several ways. While the value of bodily rest is strongly insisted upon, as in the Von Leube treatment, the withholding of food even in cases with hemorrhage is not recommended. Lenhartz believed that more could be accomplished in the way of sparing the stomach by giving frequent feedings of proteid substances to combine with the acid of the gastric juice than by leaving the stomach completely empty. He further believed that improving the state of bodily nutrition and correcting any anemia that might be present was essential to the healing of the gastric ulcer. He, therefore, advised rest in bed for a period of three or four weeks, with ice-bag to epigastrium and bismuth in the morning until cessation of hemorrhage. He gave a diet, even in cases which had had hemorrhage within an hour or two before the institution of treatment, of hourly feedings, rich in albumin, the total of which for each day was planned according to the following schedule. On the first day 2 stirred raw eggs and 200 ccm. of milk, iced, were given, increasing on each of the following days by 1 egg and 100 ccm. of milk until 8 eggs and 1,000 ccm. of milk per day were taken. Sugar 20 gr. was added to the egg on the third day, increasing 10 gr. every second day up to 50 gr. per day. Scraped raw beef 35 gr. was given on the sixth day and the same amount twice on succeeding days. Rice, boiled in milk, 100 gr., was given on the sixth day, increasing 100 gr. every second day up to 300 gr. Zwieback 20 gr. was included on the eighth day, gradually increasing to 80 gr. Raw ham 50 gr. and fresh butter 20 to 40 gr. were given on and

after the tenth day. After the fourteenth day the eggs were reduced to 2, the fluid continued at 1,000 ccm. and the diet continued at 3,000 calories a day, including, in addition to the articles previously allowed, thick soups, roast and boiled meat, mashed potato and certain other vegetables. The bowels were not stimulated to act, but were allowed to remain without movement for ten days or more unless distention occurred, in which case a low enema was given. Contrary to the common teaching that iron is harmful in gastric ulcer, iron was given in the form of a specially prepared pill of soft consistency.

Lenhartz' report includes 295 cases, — 262 with recent hemorrhage and the remaining 33 with more or less blood in the stools. Of these 295 cases, only 7 died, and of the last 120 cases, but one died. There were but 18 which had return hemorrhage after the treatment was begun. The pains ceased within a day or two and never required narcotics; throughout the treatment the patients were more comfortable than under the Von Leube treatment previously used; convalescence was more rapid, with earlier return to normal diet and to work with gain in weight.

Excellent as these results seem, Von Leube in his reply to Lenhartz at the Congress and in a subsequent article [57] has published statistics of his own treatment which are even more striking. Of 627 cases of gastric ulcer, he reports 90% cured, 8.5% improved, only 1% not improved, and mortality 0.3%. Of 80 cases with recent hemorrhage, 90% were cured, 6¼% improved, 1¼% not improved, with a mortality of 2½%; 7 cases among these 80 had recurrence of hemorrhage. Of 547 cases without hemorrhage, there was no mortality.

Thus, both of these methods in the hands of their authors have given results far better than have commonly been attained.

The Lenhartz diet has been given trial by a number of authors not only in Germany, but also in other countries of Europe and in America. The preliminary reports of Lenhartz' method, notably that published by his assistant, Wagner, [60] attracted attention which led to reports by other authors and much discussion. Wirsing [61] applied the treatment in 326 cases with highly favorable results. Minkowski [62] also obtained better results than he had previously done with the Von Leube method. He did not, however, accept Lenhartz' teaching that the treatment was begun with safety and with advantage immediately after a hemorrhage, but followed the older custom of withholding all food for a day or two after hematemesis. Senator [63] recognized the force both of Lenhartz' and of Minkowski's arguments and devised a compromise between the two by means of a diet to be more fully described later, which in his opinion could be given with greater safety than Lenhartz' immediately after hemorrhage, to be adhered to for a few days, after which treatment could be continued according to Lenhartz' directions. Haberman, [64] Lambert, [65] Brown, [66] Spriggs, [67] Crummer [68] and Craig [69] have written favorable preliminary reports in English and American journals. Zweig [70] has adopted a diet closely similar to Senator's modification of Lenhartz', but on account of losing two cases from hemorrhage regards the immediate feeding as dangerous and advises a brief period of rectal feeding chiefly to supply fluid. Mayerle [71] has used the Lenhartz treatment in 71 cases with good results, but without success equal to that of the author of the treatment. Gerhardt [72] early wrote in favor of the treatment, but the results of cases reported recently from his clinic by Lüdin, [73] compared with those of a series of earlier cases from the same clinic treated by the Von Leube method, shows a slight advantage in favor of the older treatment. Ewald [74] and Weintrand, [75] on the other hand, have opposed the Lenhartz method and have adhered to the Von Leube treatment.

In the discussion following Lenhartz' report and Von Leube's reply at the Congress in 1909, [59] Müller and Von Tabora expressed themselves unfavorable to Lenhartz' immediate feeding. Von Krehl, Gerhardt and Stintzing expressed favorable impressions from their experience with Lenhartz' method. Moritz recognized the Lenhartz treatment as of value, showing that the Von Leube treatment was not the only way of accomplisihng results, but expressed a preference for the Von Leube treatment as somewhat safer.
